1   **Abstract**

2   The melting curve of Ni has been determined to 125 GPa using laser-heated diamond anvil

3   cell (LH-DAC) experiments in which two melting criteria were used: firstly, the appearance of

4   liquid diffuse scattering (LDS) during *in situ* X-ray diffraction (XRD) and secondly, plateaux in

5   temperature vs. laser power functions in both *in situ* and off-line experiments. Our new melting

6   curve, defined by a Simon-Glatzel fit to the data where $T_M (K) = [(\frac{P_M}{18.78 \pm 10.20} + 1)]^{1/2.42 \pm 0.66} \times$

7   1726, is in good agreement with the majority of the theoretical studies on Ni melting and matches

8   closely the available shock wave melting data. It is however dramatically steeper than the previous

9   off-line LH-DAC studies in which determination of melting was based on the visual observation of

10   motion aided by the laser speckle method. We estimate the melting point (T_M) of Ni at the inner-

11   core boundary (ICB) pressure of 330 GPa to be $T_M = 5800 \pm 700$ K (2σ), within error of the value

12   for Fe of $T_M = 6230 \pm 500$ K determined in a recent *in situ* LH-DAC study by similar methods to

13   those employed here. This similarity suggests that the alloying of 5-10 wt.% Ni with the Fe-rich

14   core alloy is unlikely to have any significant effect on the temperature of the ICB, though this is

15   dependent on the details of the topology of the Fe-Ni binary phase diagram at core pressures. Our

16   melting temperature for Ni at 330 GPa is ~2500 K higher than that found in previous experimental

17   studies employing the laser speckle method. We find that those earlier melting curves coincide with

18   the onset of rapid sub-solidus recrystallization, suggesting that visual observations of motion may

19   have misinterpreted dynamic recrystallization as convective motion of a melt. This finding has

20   significant implications for our understanding of the high-pressure melting behaviour of a number

21   of other transition metals.

1. Introduction

The inner core of the Earth is perpetually solidifying at the expense of the overlying liquid outer core as the Earth undergoes secular cooling over geological time. The boundary between these two regions (the inner core boundary or ICB) is, by definition, close to the P-T condition at which the geotherm intersects the solidus of the Fe-rich core alloy. An accurate knowledge of this solidus at the ICB pressure of 330 GPa would provide an anchor for the construction of an accurate geotherm, which would in turn allow us to model more accurately the thermal and chemical structure of the Earth's core, and by extension, the overlying mantle.

Attempts to estimate the solidus of the core alloy at 330 GPa are complicated by the fact that the composition of the core alloy is itself poorly constrained and the subject of on-going research (e.g.: Fischer et al., 2013; Antonangeli et al., 2010; Aitta, 2010). However, an upper bound is provided by the melting temperature of pure Fe, given that Fe is the dominant component of the core. Although a broad range of techniques have been applied to this end, the resulting estimates for this upper bound on the ICB temperature (T_{ICB}) were, until recently, highly contradictory, spanning nearly 3000 K. The lowest published estimate is that of Boehler (1993) at 4850±200 K. This is based on a melting curve for Fe determined from visual observations of motion, interpreted as convection in a melt, up to 200 GPa in the laser-heated diamond anvil cell (LH-DAC). The highest estimate is that of Williams et al. (1987), who estimated a temperature of 7600±500 K by combining similar measurements in the LH-DAC with data from the earlier shock experiments of Brown & McQueen (1986) in which the melting temperature was determined from discontinuous changes in the sound velocity of a shocked Fe sample.

More recently, a consensus has begun to emerge toward the hot end of this range. The most recent *ab initio* molecular dynamics (MD) simulations, based on density functional theory (DFT) lead to an estimate of 6370±100 K (Alfè, 2009) while the state-of-the-art quantum Monte Carlo (QMC) simulations of Sola & Alfè (2009) give 6900±400 K. Both of these estimates compare

50   favourably with the value of 6230±500 K extrapolated from the melting curve of Anzellini et al.

51   (2013) which was determined solely on the basis of the appearance of liquid diffuse scattering

52   (LDS) during *in situ* synchrotron X-ray diffraction (XRD) measurements in the LH-DAC. The

53   shock data of Nguyen & Holmes (2004) fall close to this new curve, as does the original point

54   determined by Brown & McQueen (1986). Additionally, novel methods such as the shock melting

55   of pre-heated samples (Ahrens et al., 2002) and the detection of melting by the monitoring of

56   changes in the mean-square displacement of the Fe atom either by nuclear resonant inelastic X-ray

57   scattering (Murphy et al., 2011) or synchrotron Mössbauer spectroscopy in the LH-DAC (Jackson

58   et al., 2013) yield slightly shallower melting curves and thus somewhat lower values of T_{ICB} of

59   ~5700 K that are nevertheless within mutual error of the estimates based on the more traditional

60   methods previously described. These marginally shallower slopes are in good agreement with the

61   most recent shock melting data (Sun et al., 2005; Tan et al., 2005) as well as earlier *in situ* XRD

62   measurements in the LH-DAC (Ma et al., 2004; Shen et al., 2004; 1998). A more detailed

63   discussion of the Fe melting literature can be found in Anzellini et al. (2013).

64   Regardless of this apparent consensus, these estimates represent upper bounds on T_{ICB} that

65   will be revised downwards as the effects of alloying elements are included. The relevant alloying

66   elements that must be considered are Ni, of which there may be 5-10 wt.% in Earth's core, and one

67   or more elements lighter than Fe. The most likely candidates are some subset of Si, O, C, S and H

68   (Aitta, 2010; McDonough, 2004; Allègre, 1995), required to explain the density of both the inner

69   and outer core as determined from seismic studies (Dewaele et al., 2006; Yamazaki et al., 2012;

70   Garai et al., 2011). It is the effect of Ni that is the subject of this study.

71   The addition of Ni has the potential to reduce T_{ICB} considerably because its experimentally

72   determined melting curves, to date, are very much lower than that of pure Fe: when extrapolated to

73   330 GPa, the melting curve proposed by Lazor et al. (1993) and that based on the combined datasets

74   of Errandonea et al. (2013; 2001) and Japel et al. (2005) yield melting temperatures of 3300 K and

75   3200 K respectively which are 2400-3700 K lower than the range of Fe melting temperatures

76   described above (Fig. 1). Many topologies are possible for the liquidus in the Fe-Ni system, and on

77   the basis of the subsolidus phase relations of Kuwayama et al. (2008) and Tateno et al. (2012), two

78   likely alternatives are shown in Supplementary Figure 1. Assuming melting temperatures of 6230 K

79   for Fe (Anzellini et al., 2013) and 3300 K for Ni (Lazor et al., 1993), a simple linear interpolation

80   indicates that 10 wt.% Ni in the bulk core alloy could reduce the melting temperature by ~300 K.

81   But the depression might be much greater, especially for a topology like that shown in SF1b. Thus,

82   on the basis of the current data for melting of Ni at high pressures, a large melting point depression

83   might be the expectation in the Fe-Ni system.

84   However, as Fig. 1 illustrates, this conclusion suffers from a significant problem: although

85   the existing experimentally determined melting curves for Ni agree closely with one another, there

86   is a very considerable mismatch between these experimental curves and those determined from MD

87   simulations. These have much steeper melting slopes than their LH-DAC experimental counterparts

88   and consequently much higher Ni melting points at 330 GPa: simulations using classical potentials

89   give 5300 K (Bhattacharya et al., 2011), 5900 K (Koči et al., 2006), 6700 K (Weingarten et al.,

90   2009), 6800 K (Zhang et al., 2014b) and 10,000 K (Luo et al., 2010) while extrapolating the only

91   DFT based *ab initio* study gives 6700 K (Pozzo & Alfè, 2013). The available shock melting data for

92   Ni fall in the middle of this spread of MD melting curves (Fig. 1; Urlin et al., 1966). Although there

93   is huge variation between these MD values, even the lowest (that of Bhattacharya et al., 2011) is

94   ~2000 K higher than the estimates based on the LH-DAC experiments. The absolute reduction in

95   T_{ICB} due to the mixing of Ni with Fe is dependent on the detailed topology of the Fe-Ni system at

96   330 GPa and it is formally impossible to determine its magnitude from the melting points of the

97   end-members alone. Nonetheless, if these MD melting curves are correct, then for any given

98   topology of the Fe-Ni system, the reduction in T_{ICB} is likely to be significantly smaller than would

99   be expected on the basis of the existing experimental Ni melting curves (Fig. S1). Thus, the

100   accuracy of any estimate of T_{ICB} (and more generally, the accuracy of any Fe-Ni binary phase

101   diagram at inner core pressures) is strongly dependent upon which of the published melting curves

102   of Ni is correct.

103   The present study is primarily concerned with the geophysical implications of the melting

104   curve of Ni. However, an additional motivation concerns the high-pressure melting behaviour of the

105   transition metals in general. The striking dissimilarity between the shallow slopes of melting curves

106   determined in LH-DAC experiments and the much steeper slopes determined from MD simulations

107   is not unique to Ni, but is a well-established feature seen in a range of transition metals including

108   Mo, Ta and W (e.g.: Errandonea, 2005). As is the case with Ni, the results of shock melting

109   experiments on these elements (Mo: Nguyen et al., 2014; Hixson et al., 1989; Ta: Brown & Shaner,

110   1983; W: Hixson & Fritz, 1982) yield temperatures that are much closer to the MD simulations than

111   to the static LH-DAC experiments. This has led to postulated phase diagrams that contain additional

112   high-pressure phases designed to bring the LH-DAC experiments ($P \leq 100$ GPa; e.g. Errandonea et

113   al., 2001) and high pressure shock experiments (P < 200 GPa; Nguyen et al., 2014; Hixson et al.,

114   1989) into agreement (e.g.: Errandonea et al., 2005; Wu et al., 2009; Ross et al., 2007a; 2007b).

115   However, these hypotheses fail to explain the huge disparities between the MD simulations (e.g.

116   Cazorla et al., 2007) and shock experiments performed at lower pressures (Zhang et al., 2008) on

117   the one hand and the static LH-DAC experiments on the other at $P \leq 100$ GPa.

118   An alternative explanation for the discrepancy is that the static LH-DAC melting

119   experiments, in which visual observations of melt motion were used as the primary melting

120   criterion, are not correct. A recent study by Dewaele et al. (2010), in which the melting curve of Ta

121   was determined from the appearance of LDS during *in situ* XRD in the LH-DAC, found a much

122   steeper melting curve than the earlier LH-DAC studies (Errandonea et al., 2003; 2001) and one that

123   is in reasonable agreement with the MD simulations (Taioli et al., 2007; Liu et al., 2008). This

124   situation is qualitatively similar to the Fe melting curve, in which static melting determinations

125   based on the appearance of LDS (Anzellini et al., 2013) agree well with the MD simulations (Alfè,

126   2009; Sola & Alfè, 2009) and shock measurements (e.g.: Nguyen & Holmes, 2004) but are

127   considerably higher than earlier melting curves determined in the LH-DAC using visual

128   observations of melt motion (Boehler, 1993). It seems plausible that what is apparent in Fe and Ta

129   may well turn out to be the case for other elements, such as W, Mo and Ni.

130   To determine which of the published Ni melting curves are correct, we have collected two

131   sets of melting data, both using the LH-DAC. The first set were performed *in situ* at beam line ID-

132   27 of the European Synchrotron Radiation Facility (ESRF) in Grenoble, France (§2.2). In these

133   experiments the appearance of LDS coupled with plateaux in temperature vs. laser power functions

134   were the melting criteria. The second set of measurements were performed off-line at the School of

135   Earth Sciences, University of Bristol (§2.3), in which the observation of plateaux in temperature vs.

136   laser power functions was the sole melting criterion (as described in §2.4 and by e.g. Lord et al.,

137   2014; 2010; 2009).

138   **2. Methods**

139   *2.1 Sample assemblies*

140   Pressure was generated using Princeton-type symmetric DACs with culets ranging from 250

141   μm to 150 μm in diameter (the latter bevelled at 8° out to a diameter of 250 μm). Rhenium, initially

142   250 μm thick was indented to a pressure of 25 GPa and drilled centrally to create a sample chamber

143   ⅓ the diameter of the culet. Samples consisted of either ~5 μm thick densified foils made by

144   compressing Ni powder between diamond anvils, or discs cut from 12.5 μm thick Ni sheet (both

145   99.95% purity; Goodfellow Cambridge Ltd.) using a UV laser ablation unit. The discs were then

146   polished on both sides to a thickness of ~5 μm using 0.1 μm grade Al_2O_3 impregnated Mylar

147   lapping film and then cleaned under acetone to remove any polishing debris.

148   Samples slightly smaller than the diameter of the sample chamber were loaded between

149   form fitting discs of KCl or MgO, ~15 μm thick, that acted as both pressure medium and thermal

150   insulation. These discs were cut, also using UV laser ablation, from sheets made by compressing

151   powder in a hydraulic press. Pressure was monitored during compression (in all experiments) as

152   well as before and after laser heating (in the off-line experiments) using the fluorescence of sub-

153   micron grains of $Cr:Al_2O_3$ (ruby). In the off-line experiments, these grains were placed next to the

154   sample and between the layers of pressure medium whereas in the *in situ* X-ray diffraction

155   experiments (in which the ruby was not used to determine the pressure of the experiment) they were

156   placed next to the sample chamber, between the gasket and the diamond anvil, to simplify the

157   analysis of our XRD patterns. After loading, each cell was heated at 120°C for 1 hour under an

158   argon atmosphere before being sealed under the same conditions to remove any water adsorbed

159   during loading.

160

161

162

163   *2.2 In situ experiments*

164   Samples were laser-heated in a double-sided off-axis geometry with temperatures measured

165   spectroradiometrically from the light collected using reflective optics from a 2×2 μm area centred

166   on the 20-30 μm diameter laser-heated spot. Before the start of XRD, temperatures were measured

167   on both sides and were equalized by varying the power of the lasers; during XRD, temperature was

168   measured only on the upstream side, due to the need to remove the temperature-measuring optics

169   from the path of the diffracted X-rays on the downstream side. The laser power was increased

170   incrementally and linearly with a 3 s dwell time at each power during which the detector was

171   automatically exposed to the diffracted X-rays. Temperatures were measured continuously and as

172   often as allowed by the acquisition time of the spectrometer, which varied inversely with

173   temperature. Typical temperature steps are <100 K (Fig. 4a) and a complete heating cycle took 5-15

174   minutes to complete. For further details of the laser heating system see Schultz et al. (2005).

175   The X-ray beam (33 keV; $\lambda = 0.3738$ Å; FWHM = 3 μm) was co-aligned to the centre of the

176   laser heated spot using the X-ray induced fluorescence of either the pressure medium or the Re

177   gasket. Diffracted X-rays were collected with a MAR165 CCD detector calibrated for sample to

178   detector distance using a LaB_6 standard. The resulting patterns, masked to remove saturated spots,

179   were integrated into 1-D spectra using the Fit2D program (Hammersley, 1997) and fitted using the

180   Le Bail method (Le Bail *et al.*, 1988) as implemented in the GSAS suite of programs (Larson &

181   Von Dreele, 2000; Toby, 2001). Further details of the X-ray optics and beam-line design can be

182   found in Mezouar et al. (2005).

183   Pressure was determined before and after each melting experiment from the measured unit-

184   cell volume of the Ni sample using the Vinet equation of state (EOS) reported by Dewaele et al.

185   (2008). During laser heating, the total pressure (P_M), including the thermal pressure component,

186   P_{TH}, was determined from the sample volume and temperature using a Mie-Gruneisen-Debye

187   thermal EOS. This EOS was determined by fitting the high temperature *P-V-T* data reported in

188   Table S3 of Campbell et al. (2009) while fixing $K_{0,300}$, $K'_{0,300}$ and $V_{0,300}$ at the values of 176.7

189   GPa, 5.23 and 10.942 Å^3 atom^{-1} respectively, reported by Dewaele et al. (2008). These parameters

190   were chosen because they more accurately reproduce the room temperature P-V data reported in

191   Table S3 of Campbell et al. (2009) than do the parameters reported in their Table 1. This fit gives

192    $\gamma_0 = 2.48 \pm 0.03$, $q = 2.4 \pm 0.3$ and $\Theta_{D,0} = 415\ K$ (Knacke et al., 1991). In spite of this

193   complication, the effect of the chosen thermal EOS on our results is modest; in our highest-pressure

194   *in situ* experiment, the calculated pressure of melting at the melting temperature (T_M) of the sample

195   is 77±2 GPa using our thermal EOS (described above) and 74±2 GPa if we use the EOS parameters

196   reported in Campbell et al. (2009).

197   Melting was detected using two criteria: 1) the appearance of plateaux in temperature vs.

198   laser power curves and 2) the appearance of LDS in the XRD patterns. In all experiments we define

199   T_M as the average of the temperatures within the plateau in the temperature vs. laser power function

200   rather than using the appearance of LDS, to make our *in situ* results directly comparable to our off-

201   line data (§2.3). Because LDS was always observed after the onset of and within a temperature

202   plateau, using the appearance of LDS to define T_M makes almost no difference to our reported

203   values. Our reported uncertainties in T_M are calculated by combining the average of the analytical

204   uncertainty in the temperature measurements used to calculate T_M (2-5 K) with their standard

205   deviation (50-100 K). Similarly, P_M is defined as the average of the pressures determined from all

206   the diffraction patterns collected during the plateau used to define T_M. The uncertainties in P_M are

207   calculated in the same way, by combining the average of the uncertainties in the pressures used to

208   determine P_M with their standard deviation. In both cases errors have been combined assuming that

209   they are uncorrelated.

210   *2.3 Off-line experiments*

211   Samples were heated using the on-axis double-sided laser heating system in the School of

212   Earth Sciences, University of Bristol, which is described in detail in a previous publication (Lord et

213   al., 2014). Briefly, the system consists of two 100 W diode pumped TEM_{00} fibre lasers ($\lambda = 1070$

214   nm). Beam-shaping optics and variable beam expanders were employed in the laser path to produce

215   a flat-topped temperature profile with a diameter of 10-30 μm at the sample surface. The power to

216   the lasers was automatically increased linearly as a function of time, with a constant offset designed

217   to equalize the initial temperature of the two sample surfaces.

218   In every experiment, temperature cross-sections were measured spectroradiometrically along

219   a transect across the laser heated spot (simultaneously, on both sides) by fitting the Wien function to

220   spatially resolved spectra of the emitted incandescent light (Walter & Koga, 2004). Details of this

221   technique, the associated uncertainties and the results of ambient pressure calibration experiments

222   are all described in detail elsewhere (Lord et al., 2014; 2010; 2009). In a few experiments, the 1-D

223   spectroradiometric cross-sections were supplemented with 2-D temperature maps measured on the

224   left hand side only using a newly installed multi-spectral imaging radiometry system, based on the

225   design described in Campbell (2008). Briefly, this method involves the acquisition of images of the

226   laser-heated spot at four different wavelengths (670, 750, 800 and 900 nm) on a single CCD

227   camera. The four images are then spatially correlated, based on a calibration image of a backlit

228   pinhole with a diameter of ~2-3 μm such that, at each pixel, four intensity-wavelength data points

229   are available. Temperature and emissivity are then determined at the pixel of interest by fitting the

230   grey-body Wien function to the combined data from a 9×9 pixel box centred on the pixel of

231   interest (giving a total of 324 data points). This last step is done to smooth the measured

232   temperatures to match the optical resolution of the temperature measurement system (~3 μm; Lord

233   et al., 2014). These procedures are replicated for every pixel to give 2-D maps of temperature and

234   emissivity. This method has several advantages over traditional 1-D apertured spectroradiometry.

235   First of all, because the entire hotspot is imaged, the peak temperature can always be determined. In

236   spectroradiometry, any slight misalignment of the hot spot with the spectrometer aperture will lead

237   to an underestimation of the peak sample temperature. This is especially true during melting

238   experiments, where the hotspot may move rapidly. Secondly, because each of the images can be

239   focused independently onto the CCD, imaging radiometry should lead to the complete removal of

240   chromatic effects from the measured temperatures (Lord et al., 2014). Finally, imaging the entire

241   temperature field potentially allows us to observe the dynamic changes in sample temperature and

242   morphology that occur during melting which are only partially evident when using

243   spectroradiometry. These changes may also form the basis of an additional corroborative melting

244   criterion.

245   After quenching to room temperature, the fluorescence of the ruby closest to the location of

246   melting was used to determine the melting pressure, using the calibration of Dewaele et al. (2008).

247   The uncertainty in these measurements is obtained by combining three uncorrelated terms: one

248   which encompasses the disagreement between the various recently published ruby scales available

249   (to a maximum of ±3 GPa at 110 GPa; see Fig. 3 of Dewaele et al. 2008), a second (of ±0.5-1.0

250   GPa) to take account of radial pressure gradients and a third (±0.2 GPa) to take account of the error

251   in determining the position of the R_1 fluorescence line. To determine P_M for the off-line

252   experiments, these post-heating pressures have been corrected for the effects of thermal pressure as

253   estimated from the *in situ* experiments in which the thermal pressure was measured directly (§2.5).

254   Reported values of T_M and their uncertainties were determined as in the *in situ* experiments.

255

256   *2.4 Melt detection*

257   As described in §2.2, T_M was determined from the appearance of features, often plateaux, in

258   the temperature vs. laser power functions recorded during both the *in situ* and off-line experiments.

259   This was corroborated, in nearly every *in situ* experiment, by the appearance of LDS in the XRD

260   patterns; whenever this was the case, the LDS appeared at the same temperature as the plateau,

261   though usually at a higher laser power.

262   For an in-depth discussion of the rationale behind the use of plateaux in laser power vs.

263   temperature functions as a melting criterion, the reader is referred to Lord et al. (2014; 2010; 2009)

264   and Thomson et al. (2014). In summary, we have successfully applied this technique to a range of

265   materials, including Fe, Pt, Pb, FeS, Fe_3C, Fe_7C_3, the Fe-Fe_3C eutectic, FeSi, and NiSi and the

266   solidi in the $MgCO_3$-$CaCO_3$ and $MgCO_3$-$MgSiO_3$ systems. In the case of FeSi, Fe_3C, Fe_7C_3, the Fe-

267   Fe_3C eutectic and the eutectics in the $MgCO_3$-$CaCO_3$ and $MgCO_3$-$MgSiO_3$ systems, our melting

268   curves are corroborated by the *ex situ* textural analysis of large volume press (LVP) experiments,

269   where measurements overlap. More importantly, there are now several materials for which melting

270   temperatures have been determined using this method and are found to be in excellent agreement

271   with direct observations of melting from the appearance of LDS during *in situ* XRD. These include,

272   but are not limited to, FeSi (plateaux: Lord et al., 2010; LDS: Fischer et al., 2013), $Fe_{85}Ni_5Si_{10}$

273   (plateaux: Lord et al., 2014; LDS: Morard et al., 2011) and $Fe_{91}Si_9$ (plateaux: Fischer et al., 2013

274   and Asanuma et al, 2010; LDS: Fischer et al., 2013 and Morard et al., 2011). Most important of all

275   is the case of NiSi, in which LDS was observed to occur concurrently with plateaux in the

276   temperature vs. laser power function (Lord et al., 2014).

277

278   *2.5 Thermal pressure correction of off-line experiments*

279   To allow our off-line and *in situ* melting data to be combined, we have corrected our off-line

280   data to include the effects of P_{TH}. For these experiments, the relation $P_{TH} = \alpha K_T (T_m - T_0)$, which

281   assumes that αK_T is a constant, does not accurately reproduce our measured values of P_{TH}. Instead,

282   we have determined, by linear regression, the empirical relationship between $P_{TH} = P_M - P_{300}$ and

283   P_{300} in our *in situ* experiments (where P_{300} is the pressure measured after quenching to room

284   temperature). This relationship is presented in Fig. 2 for experiments in which the pressure medium

285   was MgO (filled circles) and KCl (open circles). In both cases the data indicate a linear correlation

286   that is slightly positive, indicating that the magnitude of the thermal pressure will increase with

287   increasing compression, as expected.

288   It is also clear that at any given value of P_{300}, P_{TH} is at least a factor of ~8 smaller when

289   KCl, as opposed to MgO, is used as the pressure medium. This is not surprising because P_{TH}

290   depends on the coefficient of thermal expansion of the sample and the compressibility of the

291   pressure medium and KCl is significantly more compressible than MgO over the *P-T* range of the

292   data.

293   The data in Fig. 2 relating to each pressure medium are fitted separately, with equal weights,

294   to a straight line, giving $P_{TH} = 7.7(23) + 0.06(5)P_{300}$ for experiments in MgO and $P_{TH} =$

295    $0.03(1)P_{300}$ for experiments in KCl (in the latter case the y-intercept was set to 0 to prevent

296   negative thermal pressures at $P < 10$ GPa). The value of P_M for each off-line experiment was then

297   calculated as the sum of P_{TH}, calculated using the relations defined above, and P_{300}, determined

298   after heating by ruby fluorescence spectroscopy. The uncertainties involved in this P_{TH} correction

299   procedure are fully propagated through to the uncertainties on the reported values of P_M (Table 1).

3. Results

The corrected Ni melting data are presented in Fig. 3 while Table 1 contains the data both with and without correction for P_{TH}. It is clear that the off-line and *in situ* measurements (squares and circles in Fig. 3 respectively) are in excellent agreement with one another, as observed in a previous study on NiSi (Lord et al., 2014). The pressure medium used, either MgO or KCl, also has no significant effect on melting temperature. Our preferred melting curve for Ni (the thick black line in Fig. 3) is an equally weighted fit to all the data, corrected for thermal pressure, using the Simon-Glatzel equation (Simon & Glatzel, 1929), that yields $T_M = [\left(\frac{P_M}{18.78 \pm 10.20} + 1\right)]^{1/2.42 \pm 0.66} \times T_0$, where $T_0 = 1726$ K (the ambient pressure melting point of Ni; Weast et al., 1985). Extrapolating this fit to the ICB pressure of 330 GPa gives $T_M = 5800 \pm 700$ K (2σ). Fitting the uncorrected data in the same manner gives $T_M = [\left(\frac{P_M}{11.65 \pm 7.93} + 1\right)]^{1/2.82 \pm 0.89} \times T_0$ (the thin black line on Fig. 3) and yields an almost identical value of $T_M = 5700 \pm 900$ K (2σ) at the ICB, suggesting that the effects of thermal pressure and the correction applied to the off-line data has no substantive effect. It should be noted that both fits are highly anti-correlated, with coefficients of -0.99; thus the uncertainties on the two fitting parameters should not be considered independent.

Fig.4 shows an example of the *in situ* measurements in which MgO was used as the pressure medium. The sample temperature increases rapidly as a function of total laser power up to 2900 K at 27.8 % (Fig. 4a). At this point the temperature drops slightly and then rises again at a slower rate until remaining essentially constant from 32.2 % laser output until the end of the experiment. Averaging these temperatures (the filled circles) gives $T_M = 2820 \pm 90$ K. At 38.8 % output (marked by the arrow) LDS appears in the XRD patterns (Fig. 4b) and grows in intensity with increasing laser power until reaching a maximum at ~43 % laser output. As in our previous study on NiSi (Lord et al., 2014), we interpret the correlation between the plateaux in the temperature vs. laser power data and the LDS signal as confirmation that the generation of the plateau is directly

324   related to melting and is thus an accurate melting criterion. There are several possible reasons as to

325   why the diffuse signal does not appear until after the onset of the plateau. Firstly, the diffuse signal

326   may not be resolvable from the background until a sufficient melt volume is produced. Secondly,

327   the melt may be mobile, making it hard to observe until the majority of the sample is melted at

328   higher laser power; it is common for melted samples to exhibit holes after quenching, suggesting

329   the melt has flowed away from the hotspot, and thus also away from the X-ray beam. Thirdly, this

330   behaviour could be due to slight misalignments between the laser heated spot and the X-ray beam.

331   When MgO was used as the pressure medium, minor reaction between the mobile melt and

332   the diamond anvils was evident in our *in situ* experiments. Fig. 5a shows a pattern collected at high

333   temperature just before melting from experiment 65A; all the peaks can be indexed to fcc-Ni and

334   MgO. After quenching (Fig. 5b), new, weak peaks appear that can be indexed using the cementite

335   (Fe_3C) structure (space group *Pnma*), with a = 4.219(1) Å, b = 4.702(5) Å, c = 6.338(6) Å and V =

336   125.7(1) Å^{-3}. These values are very close to (but slightly smaller than) the values predicted for Fe_3C

337   by Sata et al. (2010) at the post heating pressure of 56.1 GPa, suggesting that the trace phase is

338   Ni_3C, which is a known metastable phase at 1 atm, albeit with a different, hexagonal, structure

339   (Goto et al., 2008). An analysis of the relative areas of the Ni and Ni_3C peaks indicate that this

340   phase represents a maximum of 13% of the sample by volume, which corresponds to a maximum C

341   content of 0.55 wt. %. The effect of this minor contamination, which is hard to avoid, would be to

342   reduce the measured melting temperature, assuming the Ni-C system is eutectic at these conditions,

343   thus strengthening further the central conclusion of this paper that the Ni melting curve is hotter

344   than previously thought. No such reaction products were observed after quench in the only *in situ*

345   experiment in which KCl was used as the pressure medium (Fig. 5c).

346   Figs. 6 (experiment 77A at 28 GPa) and 7 (experiment 79B at 125 GPa) show examples of

347   the *ex situ* data spanning the investigated pressure range. In the case of experiment 77A, the sample

348   temperature was measured not only using spectroradiometry on both sides (the circles in Fig. 6a),

349   but also using multispectral imaging radiometry on the left hand side (the squares; see §2.3).

350   Between the start of the experiment and a laser output of ~32 %, all three temperature

351   measurements in experiment 77A are in close agreement (Fig. 6a) and the shape of the temperature

352   field remains almost unchanged (compare Fig. 6b and c). This is because in the sub-solidus state,

353   the variation in temperature is primarily a function of sample thickness. Nevertheless, the use of

354   beam-shaping optics (see §2.3) means that the temperature variation within the ~20 μm diameter

355   region on which the laser is incident (represented by the black circle in Fig. 6b) is no more than ±75

356   K. At ~32.5 % laser output, all three measurements register a sudden and transient increase in

357   temperature. This is correlated with a dramatic change in the shape of the temperature field from a

358   flat-topped Gaussian distribution to a toroidal distribution (Fig. 6d). This may be the result of a

359   sudden ring shaped tear in the sample caused by melting, leading to a sudden increase in

360   temperature in the thinned regions to ~2800 K, with a localized peak in the NW quadrant reaching

361   ~3200 K. This behaviour is often, but not always observed; it likely depends on sample thickness

362   and the strength of the pressure medium. It is not surprising that the spectroradiometric

363   measurements underestimate the peak temperature at this point (see Fig. 6a); though the 1-D

364   transect used for spectroradiometry (represented by the vertical bar in Fig. 6d) will almost certainly,

365   as in this case, intersect the hot ring of the structure in Fig. 6d, it is very unlikely that a localized

366   peak on that ring will happen to coincide with the aperture. As the laser power is increased further,

367   all three measurements plateau while the shape of the temperature field recorded on the left hand

368   side (Fig. 6f-j) changes considerably between every acquisition of data, behaviour that is indicative

369   of the presence of a mobile melt (cf. Fig. 6b and c). The sudden change in the temperature

370   distribution on melting also explains the increased disparity in peak temperature recorded by the

371   three measurements within the melting plateau as compared to the initial temperature ramp (Fig.

372   6a). It is likely that on the right hand side (the filled circles in Fig. 6a) the aperture used for the

373   spectroradiometric measurements happens to coincide with the location of the hottest part of the

374   sample surface, while the aperture on the left (the open circles) does not. It is this kind of

375   misalignment between the rapidly moving melt and the 1-D spectroradiometric aperture that likely

376   accounts for the fact that the scatter in the data in Fig. 3 (up to 300 K) is significantly larger than the

377   formal error bars on the individual data points. In this case, the value of $T_M = 2620 \pm 70$ K was

378   determined by averaging the right hand side spectroradiometric measurements and the multispectral

379   imaging radiometry measurements made on the left hand side.

380   In the manner of Fischer & Campbell (2010) we looked for melting-related discontinuities

381   in temperature vs. emissivity plots taken from our multispectral imaging radiometry data. However,

382   we did not see any features that correlated consistently with our primary melting criterion. It is

383   probable that such discontinuities, which Fischer & Campbell (2010) observed in melting

384   experiments on wüstite ($Fe_{0.94}O$), depend on there being a change in the emissivity of the sample

385   upon melting. The magnitude of this change will be material specific and perhaps is not large

386   enough to be observable in Ni.

4. Discussion

4.1 Comparison with the literature

Over the range of the measurements (to 125 GPa) our new Ni melting curve is in excellent agreement with the majority of the MD studies of Ni melting: the *ab initio* study of Pozzo & Alfè (2013), and the studies of Weingarten et al. (2009) and Koči et al. (2006) which employed classical potentials. Indeed, the study of Luo et al. (2010), which also used classical potentials, is the only non-experimental study that significantly contradicts our new melting curve (1500 K hotter at 125 GPa). In addition to the MD simulations, the two shock melting points recalculated by Pozzo & Alfè (2013), on the basis of the equations of state of liquid and solid Ni reported by Urlin et al. (1966), fall almost exactly on our new melting curve.

However, our new Ni melting curve, along with all those determined on the basis of the theoretical and shock-wave data discussed above, diverges dramatically from the melting curves determined from the previous LH-DAC studies (Japel et al., 2005; Errandonea et al., 2001; Lazor et al., 1993). At 125 GPa, these curves are at least 1200 K below that reported here. This difference is most easily explained by the different melting criteria employed in the various studies. In all three of the previous LH-DAC studies, melting was determined on the basis of the observation of motion in the 'speckle' pattern created by a green Ar laser on the sample surface during laser heating (the laser speckle method), with the assumption being that such motion represented the convection of a liquid. However, the recent work of Anzellini et al. (2013) on Fe, in which melting was determined using the appearance of LDS during *in situ* XRD in the LH-DAC suggests an alternative explanation. They observed that an earlier (lower) melting curve (Boehler, 1993) that was determined using the laser speckle method, coincided with the onset of sub-solidus recrystallization as evidenced by the rapid change in the position of saturated spots around the Debye-Scherrer diffraction rings from the Fe sample. The supplementary video (S1) accompanying this paper shows the sequence of raw 2-D diffraction patterns collected during *in situ* run 65B at $P_M = 77.4 \pm 2.2$

412   GPa (see Table 1). At the start of the experiment, semi-continuous Debye-Scherrer rings can be

413   seen from the Ni sample (the rings from the MgO pressure medium remain continuous throughout

414   the experiment). At 2530 K, several large spots appear, associated with one of the Ni rings,

415   indicative of the onset of rapid recrystallization; as the temperature rises, similar spots are present in

416   nearly every pattern, but always in different locations around the Ni rings. In the pattern marked

417   3820 K toward the end of the video, a single, continuous diffuse ring, indicative of the presence of

418   melt, appears suddenly. In this example, rapid recrystallization begins more than 1000 K before the

419   first appearance of melt, which suggests that this commonly observed pre-melting phenomenon is

420   not an accurate melting criterion. The open triangles on Fig. 3 represent the temperatures at which

421   rapid recrystallization begins in all of the *in situ* experiments on pure Ni reported here. These

422   temperatures correlate well with the earlier experimental melting curves determined in the LH-DAC

423   using the laser speckle method, which suggests that those earlier studies on Ni, as is likely the case

424   with Fe, were determining the temperature of sub-solidus recrystallization rather than melting. The

425   new results further suggest that local structures in the liquid phase do not control the gradient of the

426   Ni melting curve. Such local structures were proposed by Ross et al. (2007b) as a possible reason

427   for the low gradient of the Ni melting curve as determined by the laser speckle method; in fact, their

428   model from which the entropic effects of local liquid structure is removed matches well with our

429   new melting data, the shock compression data, and the majority of the MD based simulations (cf.

430   Fig. 3 from this paper with Fig. 4 of Ross et al. 2007b).

431   In contrast, the new Ni melting curve reported here is based on the direct observation of the

432   presence of melt from its diffuse scattering signal during *in situ* XRD experiments, and the

433   appearance of plateaux in temperature vs. laser power curves, which are themselves correlated with

434   the appearance of LDS in the *in situ* experiments. The fact that our melting curve agrees closely

435   with both the existing shock wave data and the majority of the computational studies gives us

436   confidence in its accuracy.

437

438   *4.2 Implications for the phase diagrams of the transition metals*

439   The possibility that the laser speckle method may lead to the misidentification of sub-solidus

440   recrystallization as melting has considerable implications for many other transition metals for which

441   melting curves have been determined using this method. It is well known (Errandonea et al., 2005)

442   that the laser speckle studies on the bcc metals Mo, Ta and W define melting curves which are

443   much lower in temperature than those determined from MD simulations, shock wave experiments,

444   and in the case of Ta, *in situ* XRD in the LH-DAC where LDS was used as the melting criterion

445   (Dewaele et al., 2010). Co, Ti, V and Cr (Errandonea et al., 2001) have also been studied using the

446   laser speckle method, though less extensively by MD. Nevertheless, a recent MD study on Co

447   (Zhang et al., 2014a) yet again indicates a much steeper melting curve compared to the one

448   generated using the laser speckle method. In contrast, it is also apparent that the laser speckle

449   measurements on Al (Ross et al., 2004) and Cu, Pt and Pd (Errandonea et al., 2013) are in very

450   good agreement with the available shock wave and MD melting curves. We suggest that additional

451   studies should be performed on all of these metals, using the melting criteria employed in this

452   study, to determine whether the shallow slopes genuinely represent melting, and why the laser

453   speckle method appears to define melting accurately in some materials but not others.

454

455   *4.3 Implications for the temperature at the ICB*

456   Extrapolating our melting curve to the pressure of the ICB (330 GPa) yields $T_M = 5800 \pm$

457   700 K (2σ), which falls within error of the classical MD study of Koči et al. (2006; $T_M = 5950 \pm$

458   50 K) and the cell-theory based study of Bhattacharya et al. (2011; $T_M = 5330 \pm 50$ K). In

459   contrast, the only *ab initio* MD study of Ni melting (Pozzo & Alfè, 2013) predicts a value of

460   6740±180 K, nearly 1000 K higher. This value is however, like ours, an extrapolation, with

461   simulations having only been performed to 100 GPa, all of which give values within error of our

462   new melting curve. In contrast, the *ab initio* MD study of Fe by Alfè et al (2009), which used a

463   similar method but was performed at 330 GPa, thus requiring no extrapolation, yields $T_M = 6400 \pm$

464   100 K which is very close to the value determined from the *in situ* LH-DAC experiments of

465   Anzellini et al. (2013; $T_M = 6230 \pm 500$ K). It is apparent from the above (and Fig. 3) that the

466   melting point of Ni at the ICB from this study and the value for Fe from the study of Anzellini et al.

467   (2013), both of which rely on the appearance of LDS during *in situ* XRD, are within error of each

468   other. This is also the case (albeit at a somewhat higher temperature) for the most recent *ab initio*

469   MD studies on Ni (Pozzo & Alfè, 2013) and Fe (Alfè et al., 2009). This suggests that, regardless of

470   which method is most accurate, Fe and Ni have very similar melting points at 330 GPa.

471   It is formally impossible to determine the melting point of an intermediate composition

472   within a binary system from the melting points of the end-members alone. However, our new

473   melting curve for Ni suggests that the reduction in T_{ICB} is likely to be significantly smaller than

474   would be expected were the existing experimental Ni melting curves correct (Fig. S1), further

475   bolstering claims that Earth's core is hotter than previously thought (Anzellini et al., 2013). To

476   settle this question completely, full computational and experimental studies designed to determine

477   the phase relations in the Fe-Ni binary system at core pressures are required. Nevertheless, our Ni

478   melting curve adds a significant new constraint on those phase relations.

5. Conclusions

479

480   We have presented a new melting curve for Ni to 125 GPa, based on the appearance of LDS

481   during *in situ* XRD in the LH-DAC and plateaux in temperature vs. laser power functions in both *in*

482   *situ* and off-line experiments. The new melting curve is in excellent agreement with the majority of

483   the theoretical (primarily MD) studies on Ni melting, and matches closely the available shock wave

484   data. We estimate the melting temperature of Ni at the ICB pressure of 330 GPa as $T_M = 5800 \pm$

485   700 K (2σ), which is 2500 K higher than the value of $T_M \approx 3300$ K from the studies of Lazor et al.

486   (1993), Japel et al. (2005) and Errandonea et al. (2013; 2001) which employed the laser speckle

487   method as the melting criterion but close to the value of $T_M = 6230 \pm 500$ K for Fe from the recent

488   study of Anzellini et al. (2013) as determined by methods comparable to those used here. Our new

489   melting curve for Ni suggests that the reduction in T_{ICB} is likely to be significantly smaller than

490   would be expected were the existing experimental Ni melting curves correct, further bolstering

491   claims that Earth's core is hotter than previously thought (Anzellini et al., 2013).

492   Along with FeSi (Fischer et al., 2013) and NiSi (Lord et al., 2014), this study provides a

493   further example of the accuracy as a melting criterion of plateaux in temperature vs. laser power

494   functions because, in each case, melting temperatures determined in this way correlate exactly with

495   direct observations of melting from the appearance of LDS during *in situ* XRD.

496   Analysis of our XRD patterns indicates that the earlier melting curves for Ni, determined by

497   the laser speckle method, correlate with the onset of sub-solidus recrystallization rather than

498   melting, as was observed in Fe (Anzellini et al., 2013). This has significant implications for a

499   number of other transition metals, such as Mo, W, Co, V, Ti and Cr that also exhibit shallow

500   melting slopes, but have thus far only been studied in the LH-DAC using the laser speckle method.

501   Finally, our 2-D temperature mapping, generated using multispectral imaging radiometry

502   (Campbell, 2008) shows dramatic changes on melting in the dynamics of the temperature field that

503   could be employed as a useful additional melting criterion in off-line LH-DAC studies.

685   **Figure Captions**

686

687   **Figure 1:** Comparison between the phase diagrams of Fe and Ni up to 330 GPa based on selected

688   data from the literature. Thick lines and bold labels: the Fe phase diagram of Anzellini et al. (2013);

689   thin lines: Ni melting curves. Dashed lines indicate extrapolation. Experimental Ni melting curves

690   include that of Lazor et al. (1993; L93) and a curve fitted to the combined datasets of Errandonea et

691   al. (2013; 2001; E01) and Japel et al. (2005; J05). Curves based on MD simulations include those of

692   Bhattacharya et al. (2011; B11), Koči et al. (2006; K06), Pozzo & Alfè (2013; P&A13), Zhang et al.

693   (2014b; Z14) and Luo et al. (2010; L10). The MD simulations of Weingarten et al. (2009; W09)

694   only extend to 15 GPa and so are not shown separately for clarity, but match almost exactly the

695   melting curve of Pozzo & Alfè (2013). Closed triangles: shock melting points recalculated by Pozzo

696   & Alfè (2013) on the basis of the equations of state of liquid and solid Ni reported by Urlin et al.

697   (1966).

698

699   **Figure 2:** $P_{TH} = P_M - P_{300}$ plotted as a function of P_{300} for *in situ* experiments, where P_M is the

700   total pressure determined from the volume and temperature of the sample as measured during

701   melting and P_{300} is the pressure measured after quenching to room temperature. Closed symbols, Ni

702   with MgO as the pressure medium; Open symbols, KCl as the pressure medium with samples of

703   pure Ni (empty), $Ni_{91.6(4)}Si_{8.4(4)}$ (crosses) and $Ni_{95.8(2)}Si_{4.2(2)}$ (pluses). The data from the two Ni-Si

704   alloy compositions are from unpublished experiments in which the KCl pressure medium was also

705   used as the pressure standard. The lines are equally weighted linear regressions of the data with the

706   fit for KCl forced through zero to prevent negative thermal pressures at $P < 10$ GPa.

707

708   **Figure 3:** Ni melting data collected *in situ* at the ESRF (circles) and off-line at Bristol (squares).

709   For clarity, only the data corrected for the effects of thermal pressure P_{TH} are shown. See §2.5 of

710   the text for details of the correction procedure and Table 1 for the uncorrected values. The thick

711   black line is an equally weighted fit using the Simon-Glatzel equation while the grey field is a 2σ

712   error envelope. The thin black line is a similar fit to the uncorrected data (not shown). The red open

713   triangles represent the estimated temperature of the onset of rapid recrystallization in our *in situ*

714   experiments. The grey lines represent other Ni melting curves reported in the literature based on

715   experiments (thick) and MD simulations (thin) labelled as in Fig. 1, with dashed lines representing

716   extrapolation. Closed triangles: shock melting points recalculated by Pozzo & Alfè (2013) on the

717   basis of the equations of state of liquid and solid Ni reported by Urlin et al. (1966). The black cross

718   at 330 GPa represents the melting point of pure Fe based on the *in situ* experiments of Anzellini et

719   al. (2013). Experimentally determined melting curves for the MgO and KCl pressure media are

720   from Zerr & Boehler (1994) and Boehler et al. (1996) respectively.

721

722   **Figure 4:** *In situ* run 59A (Ni in MgO at $P_M = 45.8 \pm 1.3$ GPa). (a) Temperature vs. laser power

723   plot. The grey bar represents the melting temperature determined from the points within the melting

724   plateau (filled circles). The arrow represents the laser power at which LDS was first observed; LDS

725   was observed in all subsequent data above this power, which are colour coded as a function of laser

726   power. (b) XRD patterns colour coded to match (a). The black spectrum is the pattern collected

727   immediately before the onset of LDS; the dashed line is a fit to its background. Tick marks from top

728   to bottom represent Ni in the fcc structure and MgO. A constant intensity offset is applied to each

729   pattern such that all the patterns match at $2\theta = 8°$.

730

731   **Figure 5:** Le Bail fits (red lines) and difference curves (blue lines) of XRD data (black crosses)

732   from experiment 65A immediately before melting (a) and after temperature quench (b) and from

733   experiment 35A, also after quenching (c). Upper tick marks are for fcc-Ni; lower tick marks are for

734   MgO in (a) and (b) and for B2-KCl in (c). The arrows in (b) represent a quenched trace carbide

735   phase, probably with the Ni_3C stoichiometry. The single arrow in (c) indicates a reflection from the

736   ruby pressure marker not included in the fit. See text for details.

737

738   **Figure 6:** Off-line run 77A (Ni in KCl at $P_M = 27.7 \pm 2.6$ GPa). (a) Temperature vs. laser power

739   plot. Grey bar as in Fig. 4. Spectroradiometric measurements are represented by the circles (filled

740   for the right-hand side, open for the left-hand side) while multispectral imaging radiometry

741   measurements (made on the left-hand side only) are represented by the open squares. (b-j)

742   Temperature maps determined by multispectral imaging radiometry measurements, colour coded as

743   a function of temperature. The black circle in (b) represents the approximate location of the ~20 μm

744   diameter incident laser beam while the grey bar in (d) represents the approximate location of the 3

745   μm wide aperture used for spectroradiometry. The letters b-j in (a) correspond to these temperature

746   maps.

747

748   **Figure 7:** Off-line run 79B (Ni in MgO at $P_M = 125.1 \pm 2.6$ GPa). Symbols as in Fig. 5.
