Introduction

Multiple system atrophy (MSA) is a progressive neurodegenerative disease characterized clinically by autonomic failure in addition to various combinations of parkinsonism, cerebellar ataxia, and pyramidal dysfunction. The cardinal neuropathological hallmark is argyrophilic filamentous glial cytoplasmic inclusions (GCIs) in which fibrillar aggregates of α-synuclein in oligodendrocytes are the major components.

Until recently, MSA had been defined as a nongenetic disorder, but then several multiplex families with the disease were described, triggering extensive fruitful searches for susceptibility genes in case-control association studies. Subsequently, we identified a homozygous mutation and compound heterozygous mutations of COQ2 in two multiplex families with MSA. We also found a common variant (V393A) and multiple rare variants in multiplex families with MSA.8 We also found a common variant (V393A) and multiple rare variants in COQ2, all of which lead to functional impairments in the COQ2 gene product that increase the risk of developing sporadic MSA.

Abstract

Objective: Glucocerebrosidase gene (GBA) variants that cause Gaucher disease are associated with Parkinson disease (PD) and dementia with Lewy bodies (DLB). To investigate the role of GBA variants in multiple system atrophy (MSA), we analyzed GBA variants in a large case–control series. Methods: We sequenced coding regions and flanking splice sites of GBA in 969 MSA patients (574 Japanese, 223 European, and 172 North American) and 1509 control subjects (900 Japanese, 315 European, and 294 North American). We focused solely on Gaucher-disease-causing GBA variants. Results: In the Japanese series, we found nine carriers among the MSA patients (1.65%) and eight carriers among the control subjects (0.89%). In the European series, we found three carriers among the MSA patients (1.35%) and two carriers among the control subjects (0.63%). In the North American series, we found five carriers among the MSA patients (2.91%) and one carrier among the control subjects (0.34%). Subjecting each series to a Mantel–Haenszel analysis yielded a pooled odds ratio (OR) of 2.44 (95% confidence interval [CI], 1.14–5.21) and a P-value of 0.029 without evidence of significant heterogeneity. Logistic regression analysis yielded similar results, with an adjusted OR of 2.43 (95% CI 1.15–5.37) and a P-value of 0.022. Subtype analysis showed that Gaucher-disease-causing GBA variants are significantly associated with MSA cerebellar subtype (MSA-C) patients (P = 7.3 × 10−3). Interpretation: The findings indicate that, as in PD and DLB, Gaucher-disease-causing GBA variants are associated with MSA.
V393A was observed exclusively in the Japanese population, and the carrier frequency of V393A was significantly higher in Japanese MSA patients (9.1%) than in Japanese controls (3.3–4.4%) with odds ratios of 2.1–3.0. These findings suggest that impaired COQ2 activity, which would be predicted to impair the mitochondrial respiratory chain and increase vulnerability to oxidative stress, causes susceptibility to MSA. As the association was observed only in a small proportion of MSA patients, the pathogenic mechanisms underlying MSA largely remain unknown.

In contrast to the GCIs found in MSA, neuronal inclusions containing α–synuclein, termed Lewy bodies (LBs), are observed neuropathologically in Parkinson disease (PD) and dementia with LBs (DLB). Abnormal fibrillar α–synuclein aggregation in LBs and GCIs is the common feature of PD/DLB and MSA, respectively, which collectively form a subset of neurodegenerative disorders referred to as the “α–synucleinopathies.” Intriguingly, a link between PD and MSA was reported recently based on postmortem brain examinations of familial PD patients with SNCA mutations (G51D and A53E) showing α–synuclein pathology characterized by neuronal and oligodendrogial inclusions similar to GCIs. Moreover, the risk of parkinsonism among first-degree relatives is significantly higher in MSA patients than in control subjects, and coincidence of PD and MSA within the same pedigrees has been reported. Taken together, these findings raise the possibility that MSA and PD share some genetic basis.

Glucocerebrosidase (GBA) genetic variants that have been proven to be pathogenic for Gaucher disease (GD variants) are strongly associated with PD and DLB. Initial focus upon GD variants came from a report of several families of patients with GD in which obligate or confirmed carriers frequently developed parkinsonism. As then, many studies have shown that GD variants are associated with PD and DLB.

In this study, we analyzed GBA in a large series of sporadic MSA patients and control subjects to investigate the role of GD variants in the pathogenesis of MSA.

Methods

Patients with sporadic MSA and control subjects

All patients with sporadic MSA and healthy control subjects described in the previous reports, and additional participants (210 MSA patients and 380 control subjects in the Japanese series) were enrolled in this study. Written informed consent was obtained from all participants in accordance with research protocols that were approved by institutional review boards at participating centers. The diagnoses of possible and probable MSA were made based upon current consensus criteria. A total of 574 patients with sporadic MSA and 900 control subjects were included in the Japanese series, 223 patients and 315 control subjects in the European series and 172 patients and 294 control subjects in the North American series (persons of European or Hispanic descent living in North America). Ancestry was determined by self-report on a multiple-choice questionnaire. The North American series comprised 160 persons of European descent and 12 persons of Hispanic descent in patients and 284 persons of European descent and 10 persons of Hispanic descent in control subjects. Among the 218 MSA patients in the Japanese series where information on family history was available (159 with MSA cerebellar subtype [MSA-C], 53 with MSA of the parkinsonism subtype [MSA-P] and six with MSA of undefined subtype), there were 22 MSA patients (11 MSA-C, 10 MSA-P, and one undefined subtype) who also had relatives with the clinical diagnosis of PD. Among these relatives with PD, genomic DNAs were available from five (in five families) who had siblings with MSA. Sporadic MSA patients and control subjects were recruited without reference to the presence of family history for Parkinsonism. Demographic characteristics are shown in Table 1. In the European series, the male to female ratio was significantly higher in cases than that in controls ($P = 0.0012$). In the Japanese series, the mean age at examination was significantly older in cases than that in controls ($P < 0.0001$). The MSA-P to MSA-C ratio was significantly higher in the North American series than that in the Japanese series and the European series ($P < 0.0001$ and $P < 0.0001$, respectively).

Multiplex families with MSA

Independent of the sporadic case–control series, six previously described multiplex Japanese families (1–4, 8, and 12: same families with those in a previous report) were also screened for GBA variants. Autopsy findings of two affected members in Family 1 and III-6 in Family 8 confirmed the diagnosis of MSA. As previously reported, affected members in Family 1 carried the homozygous M128V-V393A variant in COQ2 and those in Family 12 carried the compound heterozygous R387X/V393A variants in COQ2.

Nucleotide sequence analysis of GBA

Polymerase chain reaction products were subjected to direct nucleotide sequence analysis of coding sequences and flanking splice sites of GBA with a DNA analyzer, 3730xl (Life Technologies, Carlsbad, CA). Three primer pairs were designed selectively to amplify GBA but not its pseudogene, as previously described. Analysis of sequence traces was achieved using Variant Reporter v1.1.
(Life Technologies) and by manual inspection of electropherograms. All sequencing analysis was performed at the Medical Genome Center, The University of Tokyo Hospital.

**Nomenclature of GBA variants**

Amino acid numbering of GBA variants followed conventional nomenclature, which considers the first amino acid after the signal peptide (the first amino acid of the mature GBA protein) as amino acid 1.21

**Gaucher-disease-causing GBA variants**

We referred to the Human Gene Mutation Database (HGMD) Professional 2014.1 (BIOBASE, Beverly, MA) for information about GBA variants. The variants that were categorized as “disease-causing mutations” for GD in HGMD are hereinafter termed GD variants. In this study, we focused solely on GD variants, which included 256 missense variants, 19 splicing variants, 28 small deletions, 15 small insertions, four small indels, four gross deletions (defined as more than 20 base-pairs), one gross insertion, and 18 complex rearrangements.

**Statistical analysis**

Results are presented as means and standard deviations. We used Student’s t-test to determine whether the mean age at disease onset between carriers and noncarriers of the GD variants were significantly different. We used Fisher’s exact test and multiple logistic regression analysis to compute odds ratios and corresponding 95% confidence intervals (CIs). We calculated pooled odds ratios based on a fixed-effects model (Mantel–Haenszel method) and a multiple logistic regression model. The heterogeneity across odds ratios was assessed with Cochran Q statistic, Breslow-Day test, and I^2 statistics. All statistical tests were two-sided, and we used a P-value of less than 0.05 to indicate statistical significance. Our statistical analysis utilized StatsDirect version 2.7.8 (StatsDirect, Cheshire, England) and R version 2.15.3 (http://r-project.org/).

**Results**

We identified 20 nonsynonymous single-nucleotide substitutions and one complex multiple-nucleotide substitutions (L444P-A456P-V460V or RecNciI) in our sporadic case–control series. Among these 21 variants, nine were known GD variants (R120W, G202R, F213I, N370S, G377S, D409H, L444P, L444R, and RecNciI) (Table 2), that is, all nine have been proven to be pathogenic for GD, which were identified only in cases with clinical features of GD and decreased GBA activities.22–29 The other 12 variants have not been reported to be pathogenic for GD, and include I(-20)V, P55L, Q57R, L67Q, R163Q, I204M, E326K, T334I, F347L, T369M, T410R, and I489V (Table S1). Of note, it has been shown that activities of mutant GBA with E326K are slightly to moderately decreased. The consensus is that E326K is not sufficient to cause GD, and a functional polymorphism.30 With these considerations, we did not include E326K as GD-causing mutations.

In the Japanese series, we found nine carriers of GD variants among 574 MSA patients (1.65%) and eight carriers among 900 control subjects (0.89%). In the European series, we found three carriers among 223 MSA patients (1.35%) and two carriers among 315 control subjects (0.63%). In the North American series, we found five carriers among 172 MSA patients (2.91%) and one carrier among 294 control subjects (0.34%). Combining all series, we identified 17 carriers among 969 MSA patients (1.75%) as GD variant carriers, and we found GD variant carriers in 11 of the 1509 control subjects (0.73%). Among carriers of GD variants, two MSA patients (one MSA-C from the European series and one MSA-P from the North American series) carried homozygous N370S variants, whereas none of the control subjects had two alleles with GD variants. The ages at onset of the

MSA-C and MSA-P patients were 43 and 69, respectively. The available medical records of the two cases made no mention of GD or relevant clinical signs.

Although the carrier frequencies of GD variants were higher in MSA patients than in control subjects within the three series, the difference was significant only in the North American series ($P = 0.028$). A Mantel–Haenszel procedure of each series yielded a pooled odds ratio (OR) of 2.41 (95% CI 1.14–5.21) and a $P$-value of 0.029 (Fig. 1). The heterogeneity of OR of each series from the Mantel–Haenszel analysis was not significant (Cochran $Q = 1.80, P = 0.41$; Breslow-Day = 1.99, $P = 0.37$; $I^2 = 0$%). A multiple logistic regression model employing GD variants in each series yielded an OR adjusted for each series of 2.43 (95% CI 1.15–5.37, $P = 0.022$), and an unadjusted OR of 2.43 (95% CI 1.15–5.37, $P = 0.022$) (Table 2). Taken together, these data indicate that there is no effect modification by the series.

We then analyzed the clinical presentations of the 17 MSA patients carrying GD variants. The ages (in years) at symptom onset in these patients (58.1 ± 8.2) did not differ significantly ($P = 0.93$) from those in noncarriers (57.9 ± 8.9). The male to female ratio of these patients (8:9) did not differ significantly ($P = 0.47$) from those of noncarriers (540:412). The clinical phenotypes of these 17 MSA patients included 14 MSA-C and three MSA-P subjects (Table 3). The carrier frequency of MSA-C patients was 2.17% (14 in 646) and that of MSA-P patients was 1.11% (3 in 270). None of the 53 patients with undefined subtypes carried GD variants. Given that 11 in 1509 control subjects (0.73%) carried such variants, GD variants were significantly associated with MSA-C (adjusted OR, 2.99 [95% CI 1.35–6.79], $P = 7.3 \times 10^{-3}$). In the MSA-C group, a Mantel–Haenszel procedure of each series yielded a pooled OR of 3.00 (95% CI 1.37–6.59) with a $P$-value of $6.3 \times 10^{-3}$ (Fig. S1). The heterogeneity of OR of each series from the Mantel–Haenszel analysis was not significant (Cochran $Q = 2.82, P = 0.24$; Breslow-Day = 3.48, $P = 0.18$; $I^2 = 29$%). Although the carrier frequency is also higher in MSA-P patients than in control subjects, the association of GD variants with MSA-P is inconclusive (adjusted OR, 1.54 [95% CI 0.34–5.04], $P = 0.51$).

Interestingly, we occasionally see siblings or other family members of the patients with MSA who are affected with PD. Among the five sib-pairs with sporadic MSA and PD, where genomic DNA samples are available (Families P2, P29, P30, P31, and P32 in Fig. 2), one sib-pair (Family P29) share the same heterozygous GD mutation, G202R. In another sib-pair (Family P2), one PD patient discordantly had a heterozygous GD variant (RecNciI). SNCA single-nucleotide substitutions and multiplications were not present in the affected members of these pedigrees (data not shown).

Independent of the above analyses, we additionally analyzed affected members in six multiplex families with MSA reported previously.8 Of the six multiplex MSA

GBA, Glucocerebrosidase; MSA-C, multiple system atrophy of the cerebellar type; MSA-P, multiple system atrophy parkinsonism subtype; NM, nonmutated allele; NA, not applicable.
families, we found that three of the four patients with MSA in Family 8 had GD variants, whereas we did not observe GD variants in other families. In Family 8, three patients with MSA-P (III-2, III-4, and III-6) including one (III-6) with autopsy-proven MSA (definite MSA) had the same heterozygous GD variant (L444R) (Fig. 3), whereas the other patient with MSA-C (IV-1) did not carry the variant. In addition, one unaffected sibling (III-5) carried the variant, whereas the other unaffected sibling (III-1) did not carry the variant. Thus, although cosegregation of the GD variant with MSA was not complete in this family, the observation may also support some association of GD variants with MSA.

**Discussion**

In this study, we demonstrated that GD variants are associated with MSA, raising a possibility that MSA, PD, and DLB partly share genetic risk factors. The carrier frequency of GD variants in MSA is 1.75% in the combined Japanese, European, and North American series. This is in a striking contrast to a much higher carrier frequency of ~7% in PD, suggesting that impact of GD variants as a risk factor for MSA is weaker compared to that for PD.17

We focused solely on GD variants that have been reported to be pathogenic mutations for GD, and this makes it difficult to interpret the pathogenicity of other rare variants that have not been reported to cause GD. As a considerable number of rare variants with unknown significance were identified in this study, functional analysis of each mutant GBA would be required to determine whether they are functionally neutral variants or potentially pathogenic for GD.

Diagnosis of MSA was made according to the current consensus criteria in this study. Although there is an inherent risk for clinical misdiagnosis, which would limits the interpretations of our findings, it should also be noted that to evaluate associations of rare variants with diseases as encountered in this study, substantially large sample sizes are required to accomplish a sufficient detection power. Nonetheless, it is noteworthy that GD variants were significantly associated with MSA-C, given that the clinical
presentation of MSA-C is distinct from that of PD and inclusion of patients with PD in the MSA-C group is unlikely.1 Although the carrier frequency is also higher in MSA-P patients than in control subjects, the association of GD variants with MSA-P is inconclusive. Given their limited sample size (n = 270) in this study, analysis of a larger case series will be needed to answer the question of whether GD variants are also associated with MSA-P.

In the five sib-pairs with coincidence of MSA and PD and the six multiplex families with MSA, it is noteworthy that, despite the low frequency of carriers of the GD variants in the Japanese controls (0.89%), GD variants were identified, and shared by affected siblings in Family P29 (one sibling with MSA-C and one with PD) and Family 8 (three siblings with MSA-P). None of the affected individuals (either MSA or PD) carried deleterious variants in COQ2 (data not shown). Although the number of families is limited and cosegregation is not complete in Family 8, these observations may support the increased risk of GD variants in developing MSA, leading to familial clustering.

In our previous study, we showed that the carrier frequency of V393A in COQ2 was significantly higher in Japanese MSA patients (9.1%) than in Japanese controls (3.3–4.4%) with odds ratios of 2.1–3.0. It is remarkable that among the nine MSA patients carrying GD variants in the Japanese series, two MSA-C patients had GD variants (one F213I and one L444P) and V393A variants in COQ2 simultaneously, both in heterozygous states (data not shown). Their ages at onset were both 54 years, which is slightly younger than the average age at onset of 58.7 years in the Japanese MSA patients. As the number of patients carrying both alleles is limited, the biological relevance of the combination of GBA and COQ2 variants in the pathogenesis of MSA remains to be determined.

Previous studies have shown no significant associations of GD variants with MSA,31–34 perhaps because of smaller sample sizes, and perhaps because these studies analyzed only specific variants (L444P and/or N370S). The concordant trend of increased risk of GD variants for developing MSA in each of the three series utilized in this study (Japanese, European, and North American) strengthens our conclusion and makes a bias of stratification unlikely.

Since discovery of the genetic association between GBA and PD, the biological relationships between mutant GBA...
and α-synuclein have been investigated intensively. Use of induced pluripotent stem cells from PD patients with GD variants revealed that GBA activity was reduced, glucosylceramide and α-synuclein levels were increased, and both autophagy and ubiquitin-proteasome pathways were defective in derived dopaminergic neurons.35 Moreover, a postmortem human brain study showed that, even in sporadic PD patients without GD variants, GBA activity in the early stages of PD within regions containing increased α-synuclein levels and limited LB formation.36 While future replication studies on larger case-control series would be needed to verify the association of GBA mutations with MSA, studies on the biochemical effects associated with mutant GBA may contribute to better understanding the mechanisms underlying development of MSA as well as those underlying PD, and aid in developing novel therapeutic measures for this intractable disease.

Acknowledgments

This study was supported in part by KAKENHI (Grant-in-Aid for Scientific Research on Innovative Areas [22129001 and 22129002]) to S. T.; the Global COE Program from the Ministry of Education, Culture, Sports, Science and Technology of Japan, a Grant-in-Aid (H23-Jitsuyoka [Nanbyo]-Ippan-004, and “the Research Committee for Ataxic Diseases” of the Research on Measures for Intractable Diseases) from the Ministry of Health, Welfare and Labour, Japan to S. T.; the French Agency for Research (ANR-09-MNPS-032-01/R09148DS) and the Programme Hospitalier de Recherche Clinique (AOM03059/R05129DD) to A. D. and A. B.; the Deutsche Forschungsgemeinschaft (Wu 184-6) the Deutsche Parkinsonvereinigung to U. W.; National Institutes of Health grant (P01NS044233) to P. A. L. We thank Mio Vereinigung to U. W.; National Institutes of Health (NS-53488) to J. Q. T.; and National Institutes of Health grant (P01NS044233) to P. A. L. We thank Mio Takeyama, Keiko Hirayama, and Zhenghong Wu for their support in the laboratory experiments and Cecilia Marelli for her clinical input to this study. We also thank the DNA and Cell Bank of CRicm for technical assistance.

Figure S1. Odds ratios for Gaucher-disease-causing GBA variants among MSA-C patients, as compared with controls, at each case–control series and overall. Shown are the combined estimates (on a log 10 scale) of the odds ratios for carrying GD variants among MSA-C patients. The odds ratio estimate is marked with a solid black square. The lines represent the 95% confidence interval of odds ratio estimate. The size of the square represents the weight that the corresponding series exerts in the Mantel–Haenszel analysis. Confidence intervals of pooled odds ratios are displayed as a horizontal line through the diamond. The heterogeneity of odds ratio of each series from the Mantel–Haenszel analysis was not significant (Cochran Q = 2.82, P = 0.24; Breslow-Day = 3.48, P = 0.18; I² = 29%), indicating that there is no effect modification by the series (population).

Table S1. Nonsynonymous variants in GBA that have not been reported to be causative for Gaucher disease.
