Purpose: Calcium stones represent 85% to 90% of all urinary calculi, including various crystalline compositions and etiological conditions. Calcium phosphate accounts for 10% to 15% of cases. These stones are mainly related to 3 groups of risk factors, including calcium or phosphate metabolism disturbance, renal acidification defects and urinary tract infection. Identifying the stone etiology often requires extensive metabolic evaluation. We assessed whether stone analysis including morphological typing in addition to stone composition could be a valuable help for diagnosis.

Materials and Methods: Of 60,564 stones analysed by morphological examination and infrared spectroscopy at our laboratory 6,439 (10.6%) were mainly composed of carabapatite. Of these stone 1,093 patients were included in study who had an available etiological diagnosis and stones containing at least 70% of calcium phosphate without struvite.

Results: Of the 1,093 calcium phosphate stones 12.8% showed a peculiar morphology termed IVa2, characterized by a smooth aspect and a glazed brown yellow appearance with tiny cracks. This was associated with inherited distal renal tubular acidosis in 96.1% of cases. In contrast, the other stones of similar composition but different morphology were related to distal renal tubular acidosis in only 3.9% of cases. In addition, IVa2 stones were found in 65% of calcium phosphate stone formers associated with Sjögren syndrome and in 35% of calcium phosphate stones in patients with medullary sponge kidney. These 2 conditions are related to a mild to moderate distal acidification defect.

Conclusions: Identifying IVa2 stone morphology is clinically relevant because it should prompt clinicians to search for complete or incomplete distal acidosis and initiate specific therapy to decrease recurrence.

KeyWords: kidney; nephrolithiasis; calcium phosphate; acidosis, renal tubular; diagnosis

Introduction

Nephrolithiasis is a common disease affecting more than 10% of the population in Western countries with a high recurrence rate. The annual cost in the United States was \$2 billion in 2000 and it is increasing with time [1]. The causes are diverse, including dietary disequilibrium, urinary tract infection and metabolic disorders related to acquired or genetic diseases. Although stone classifications commonly distinguish only few chemical compounds, namely calcium, uric acid, cystine and infection stones, physical analysis may identify a wide variety of components. More than 100 mineral or organic compounds have been identified to date [2]. In industrialized countries and in an increasing number of developing countries so-called calcium stones account for about 90% of all urinary calculi with calcium oxalate the most frequent chemical species [3-5]. However, calcium stones can be divided into subgroups according to the main crystalline phase, which is often a strong marker of a specific urine composition [6]. Of the calcium phosphate stones those of carbapatite (crystallized carbonated hydroxyapatite) may result from urinary tract infection or metabolic factors such as hypercalciuria, phosphate leak or tubular acidification defects.

Although rare, some genetic or acquired diseases may be responsible for severe forms of urolithiasis associated with nephrocalcinosis and end stage renal failure, especially when the diagnosis is delayed. For example, in primary hyperoxaluria cases stone morphology and not composition could help with the diagnosis [7]. Thus, stone morphology appears to be a convenient, straightforward and useful examination to diagnose this rare but severe pathological composition while stone composition alone does not lead to the diagnosis.

Based on this background we hypothesized that other varieties of stones could benefit from morphological examination. An example would be calcium phosphate stones, which account for 10% to 15% of all calculi and result from urinary tract infections and/ or different metabolic disorders such as idiopathic hypercalciuria, hyperparathyroidism, phosphate leak, tubular acidosis or an excessive alkali load [8,9].

The advantage of adding a stone morphology examination to infrared analysis is to provide a rapid, inexpensive orientation to specific pathological conditions that could not be readily identified when extensive metabolic investigations are not systematically performed. For example, in our experience the identification of typical IVa2 morphology led to the diagnosis of poorly symptomatic Sjögren syndrome with incomplete dRTA.

We sought to provide evidence that in addition to infrared spectroscopy, determining stone morphology is a key step in the diagnostic procedure of stone analysis that may identify sometimes unexpected metabolic or monogenic related stone diseases.

Patients and Methods

Of 60,564 stones analysed by morphological examination and infrared spectroscopy at our laboratory 6,439 (10.6%) were mainly composed of calcium phosphate (more than 50% of the stone mass), including carbapatite, brushite, octacalcium phosphate pentahydrate, amorphous carbonated calcium phosphate or whitlockite. Of the stones 5,181 were mainly composed of carbapatite, representing 80.5% of calcium phosphate stones and 8.5% of the whole series. Stones containing any proportion of struvite, which more specifically indicates urinary tract infection with ureolytic microorganisms, were excluded from analysis. Because Calcium phosphate may be associated with a high proportion of calcium oxalate in a number of cases and, thus, be related to various metabolic conditions, we selected only stones containing an unambiguously high proportion of calcium phosphate, namely 70% of the whole stone content on infrared spectroscopy. Finally, we included in study only calculi

associated with a detailed etiological diagnosis provided by physicians, which was available for 1,093 patients.

Of the relevant diagnoses dRTA was diagnosed first based on low serum bicarbonate, moderately low arterial pH (excluding pulmonary alkalosis), low urine ammonium, urine pH greater than 6.5 and in some cases a bicarbonate load test. In addition, when measured, urine citrate was low in the absence of urinary tract infection, commonly less than 0.7 mmol per 24 hours. The diagnosis of inherited dRTA was proven by DNA sequencing of the $\text{Cl}^- \text{HCO}_3^-$ exchanger gene (SLC4A1) or the H^+ adenosine triphosphatase gene (ATP6V0A4 or ATP6V1B1). MSK was diagnosed by computerized tomodensitometry or excretory urogram. Sjögren disease was diagnosed by at least 4 classic criteria, including a salivary gland biopsy based Chisholm score of greater than 3 and autoimmunity.

Morphological Examination and Infrared Analysis

Each calculus was studied using a stereomicroscope to define morphological type and structural characteristics as previously described.¹⁰ This also enabled the selection of representative parts of the stone for infrared analysis, such as the nucleus, the inner and external layers, and the surface [11]. Spectra were recorded by a Spectrospin Vector 22 Fourier transform infrared spectrometer (Bruker, Karlsruhe, Germany). Figure 1, a shows the $\frac{1}{2}F1$ typical spectra of carapatite stones.

SEM and Statistics

A SUPRA 55-VP type environmental SEM (Carl Zeiss, Oberkochen, Germany) was used to observe the microstructure. This field effect gunmicroscope operates at 0.5 to 30 kV. High resolution observations were made using 2 secondary electron detectors, including an in-lens secondary electron detector and an Everhart-Thornley secondary electron detector. An important feature of the environmental SEM compared to a conventional SEM is that nonconductive materials can be imaged without a conductive coating, which permits direct observation with no damage to the sample. The Fisher exact test was used for statistical comparison between groups. Statistical analysis was done with NCSS software.

RESULTS

While the infrared spectra of carapatite stones were similar, the stones showed 2 morphological types (see Appendix and fig. 1, a to c). Stones of the first type, which was more common, had a homogenous rough surface and a poorly organized section of diffuse, whitish, concentric layers (fig. 1, b). The second type of stones showed a peculiar morphology characterized by a homogeneous smooth surface with a glazed appearance, bumps and cracks, and a heterogeneous inner organization of yellow-brown concentric foliated structures (fig. 1, c). In a previous morphoconstitutional classification of stones the 2 morphologies were termed types IVa1 and IVa2, respectively.¹⁰ The ultrastructure revealed by SEM confirmed a different stone pattern between the 2 morphological types (fig. 1, d and e).

Figure 1. a, typical FTIR spectroscopy spectra of IVa2 and IVa1 type kidney stones. b, external and internal optical images of IVa1 type. c, external and internal optical images of IVa2 type. Arrows indicate surface cracks. d, SEM image shows type IVa1. e, SEM image shows type IVa2. d and e, scale bar indicates 10 μ m.

Of the 1,093 stones containing more than 70% calcium phosphate IVa1 stones were more common (87.2% of cases) than IVa2 stones. They were mainly related to chronic urinary tract infection in 39.6% of cases, hypercalciuria in 25%, MSK in 17% and primary hyperparathyroidism in 9.8% (see table 1).

Table 1. IVa1 and IVa2 types among mainly Ca phosphate calculi by etiology ($p < 0.0001$).

Etiology	No. Stones	No. Pts IVa1 (%)	IVa2			
			No. Pts (%)	% Sensitivity	% Specificity	
Inherited dRTA	77	3 (3.9)	74 (96.1)	96.1	93.5	
Sjögren syndrome	20	7 (35.0)	13 (65.0)	65.0	88.2	
Carbonic anhydrase inhibitors (acetazolamide or topiramate)	52	50 (96.2)	2 (3.8)	3.8	86.7	
MSK	211	162 (76.8)	49 (23.2)	23.2	89.7	
Primary hyperparathyroidism	93	93 (100.0)	0	—	—	
Urinary tract infection	379	377 (99.5)	2 (0.5)	—	—	
Idiopathic hypercalciuria	238	238 (100.0)	0	—	—	
Phosphate leak	23	23 (100.0)	0	—	—	
Totals	1,093	953 (87.2)	140 (12.8)	—	—	

In contrast, IVa2 stones, representing only 12.8% of carapatite stones, were associated with inherited dRTA in 52.9% of cases, MSK in 35% and Sjögren syndrome in 9.3%. Thus, the specificity of IVa2 calculi for these 3 diseases was excellent at 94.3%. The IVa2 type was found in 96.1% of the 77 cases of inherited dRTA diagnosed in this series vs less than 1% of IVa1 CA stones, representing 93.5% specificity ($p < 0.00001$). Figure 2 shows the distribution of carapatite stone types by etiology. In 3 cases the peculiar IVa2 stone morphology prompted us to search for inherited dRTA, which was confirmed by further metabolic evaluation. In another 3 cases the IVa2 stone morphology led to the diagnosis of Sjögren syndrome.

DISCUSSION

Kidney stones containing calcium phosphate are divided into 4 morphological types based on infrared analysis [2], including types IVa1 and IVa2-carapatite, IVb-mixtures of carapatite with other calcium or magnesium phosphates, IVc-struvite (excluded in this study) and IVd- brushite. A number of these stones are clearly distinguished by infrared analysis, for example brushite stones (IVd stones) or mixtures of various calcium and/or magnesium phosphates as in IVb stones. In the last 20 years we found a dramatic decrease in the incidence of infection stones related to urea-splitting bacteria while the proportion of IVb stones constantly decreased. Ambiguity remains for calcium phosphate stones mainly composed of carapatite without struvite. As previously reported some of them may be related to urinary tract infection due to the high carbonate content found on infrared spectroscopy [12]. Carapatite rich calcium phosphate stones may have 2 distinct morphologies (types IVa1 and IVa2) while the infrared spectra are often similar (fig. 1, a). We deliberately selected calculi mainly composed of carapatite with a greater than 70% calcium phosphate level.

Figure 2. Carapatite stone types by IVa1 and IVa2 etiology, including 0.3% and 52.9% for dRTA, 17.0% and 35.0% for MSK, 0.7% and 9.3% for Sjögren syndrome, 5.2% and 1.4% for carbonic anhydrase inhibitors (CAI), 9.8% and 0.0% for primary hyperparathyroidism (PHPT), 25.0% and 0.0% for idiopathic hypercalciuria (IH), 39.6% and 1.4% for urinary tract infection (UTI), and 2.4% and 0.0% for phosphate leak, respectively. Asterisk indicates $p < 0.001$ vs IVa1.

As noted in the current study IVa1 and IVa2 stones are associated with different pathological conditions. The main causes of IVa1 stones are those commonly reported in the literature for calcium phosphate stones, ie urinary tract infection, hypercalciuria and primary hyperparathyroidism [13-15]. In contrast, type IVa2 stones appear specific to inherited dRTA (see table). Interestingly IVa2 calculi are not associated with proximal tubular acidosis since stones in 96.2% of patients treated with carbonic anhydrase inhibitors, which induce proximal and distal tubular acidosis, were mainly type IVa1. Thus, IVa2 stone formation seems to depend on sustained high pH in the distal part of the nephron lumen, a setting present in dRTA due to H₂O secretion defects [16]. The typical metabolic acidosis profile may be missing in incomplete dRTA. Sjögren syndrome and MSK are significantly associated with high urinary pH related to incomplete distal acidosis, ie an acidification defect affecting only the distal segment of some nephrons [17-19]. In 1 series a distal acidification defect was observed in up to 40% of patients with MSK [20]. However, another study failed to show evidence of an acidification defect in a significant proportion of patients with MSK [21]. In clinical practice the MSK diagnosis is difficult to assess by excretory urogram as suggested by discrepancies in the incidence of MSK in stone forming patients in the literature (range 3.5% to 21%) [22-24]. These discrepancies are due to various criteria used to diagnose MSK. Until the recent optimization of diagnostic methods based on computerized tomography the identification of MSK anatomical defects was complex [25]. In our experience calcium oxalate (67.4%) and calcium phosphate (26.7%) were the main component of stones in 576 patients with MSK (unpublished data). IVa2 stones were noted only in 8.2% of cases. Thus, MSK appears to be a heterogeneous entity. The previously demonstrated link between IVa2 and distal acidosis suggests that IVa2 stones in patients with MSK would be the hallmark of a local acidification defect responsible for incomplete renal tubular acidosis. In cohorts of patients with Sjögren syndrome renal involvement was estimated to be between 25% and 40%. In clinical practice it is not always easy to make the diagnosis because metabolic disorders may be absent or not specific, such as hypocitruria, which is a common finding in nephrolithiasis cases. Thus, hypocitruria is not pathognomonic for distal tubular defect because it is often found in patients with another condition such as urinary tract infection as well as in idiopathic calcium stone formers [29]. Moreover, Sjögren syndrome may be poorly symptomatic. In our experience identifying the typical IVa2 stone morphology led to the diagnosis in several cases.

Our series clearly shows the strong link between dRTA and IVa2. Among other etiologies we found a high rate of the IVa2 type in calcium phosphate stones in patients with Sjögren syndrome (65%) or MSK (23.2%), suggesting that patients with such a stone morphology have a defect of distal acidification. Thus, an early diagnosis first indicated by typical IVa2 stone morphology may have major clinical relevance.

The high prevalence of inherited or acquired dRTA in IVa2 stone group (136 patients or 97%) may also explain why IVa2 stones are more active and recurrent than IVa1 stones. In our series 79.8% of patients with IVa2 stones had multiple recurrent stone episodes while the recurrence rate was only 54.7% in patients with IVa1 stones ($p < 0.0001$).

Thus, this high risk population deserves reinforced medical management that especially focuses on water and alkali intake. In contrast to IVa1 stones, no primary hyperparathyroidism, idiopathic hypercalciuria or phosphate leak (also called type III hypercalciuria) was observed in IVa2 stone cases. This provides interesting clinical clues and evidence that a high urinary calcium rate is not associated with this specific morphological type.

Our study has limitations. 1) It was based on a declarative diagnosis by physicians who completed a detailed form including all relevant diagnoses, limiting the study to 1,093 patients. 2) The MSK diagnosis is often complex. Incomplete distal tubular acidosis may be

under diagnosed in the absence of an acidification test. It could be interesting to assess whether a IVa2 stone is a feature of underlying acidosis in MSK cases, which deserves further study.

CONCLUSIONS

To our knowledge our data address a new paradigm in stone disease and demonstrate the interest in stone morphology analysis in addition to composition, as recently suggested by Williams and McAteer [30]. For the patient it appears highly effective and beneficial to assess an unexpected etiology that is often responsible for recurrent calculi and/or progressive renal failure, or to link/exclude stone disease using metabolic or pathological findings. For the first time to our knowledge our study shows the strong, specific link between dRTA and carbapatite stone morphological type IVa2 irrespective of the cause of dRTA. Notably stone disease may be the most prominent sign of acquired tubular acidosis before extrarenal manifestations. In such cases stone morphology provides strong evidence of dRTA.

Thus, it allows for early diagnosis and subsequent early medical management, which helps prevent the progression of chronic kidney disease. In addition to infrared spectroscopy analysis, stone morphology appears to be a major analytical step to make an etiological diagnosis of calcium phosphate kidney stones, as previously illustrated for calcium oxalate monohydrate stones in primary hyperoxaluria cases [7].

APPENDIX

Main morphological differences between IVa1 and IVa2 stone types.

Stone Morphological Characteristics	IVa1	IVa2
Surface:		
Aspect	Rough	Smooth
Bumps	Rare	Common
Glazed appearance	No	Yes
Tiny cracks	No	Yes
Color	Whitish to beige	Brown-yellow
Section:		
Crumbly, poorly organized or homogenous, diffuse whitish concentric layers	Yes	No
Foliated structure of thin whitish layers alternating with thick brown-yellow layers	No	Yes
Glazed appearance	No	Yes
