ABSTRACT

The low temperature heat capacities of Na_4UO_5 and Na_4NpO_5 have been measured for the first time in the temperature range (1.9 to 292) K using a Quantum Design PPMS (Physical Property Measurement System) calorimeter. The experimental data have been fitted to theoretical functions below 20 K, and to a combination of Debye and Einstein functions above this temperature. The heat capacity and entropy values at $T = 298.15$ K have been derived as $C_{p,m}^{\circ}(\text{Na}_4\text{UO}_5, \text{cr}, 298.15 \text{ K}) = (220.6 \pm 6.7) \text{ J} \cdot \text{K}^{-1} \cdot \text{mol}^{-1}$, $S_m^{\circ}(\text{Na}_4\text{UO}_5, \text{cr}, 298.15 \text{ K}) = (247.5 \pm 6.2) \text{ J} \cdot \text{K}^{-1} \cdot \text{mol}^{-1}$, $C_{p,m}^{\circ}(\text{Na}_4\text{NpO}_5, \text{cr}, 298.15 \text{ K}) = (219.0 \pm 6.6) \text{ J} \cdot \text{K}^{-1} \cdot \text{mol}^{-1}$, and $S_m^{\circ}(\text{Na}_4\text{NpO}_5, \text{cr}, 298.15 \text{ K}) = (247.5 \pm 6.2) \text{ J} \cdot \text{K}^{-1} \cdot \text{mol}^{-1}$. When combined with the enthalpies of formation reported in the literature, these data yield standard entropies and Gibbs energies of formation as $\Delta_f S_m^{\circ}(\text{Na}_4\text{UO}_5, \text{cr}, 298.15 \text{ K}) = -(520.8 \pm 6.3) \text{ J} \cdot \text{K}^{-1} \cdot \text{mol}^{-1}$, $\Delta_f S_m^{\circ}(\text{Na}_4\text{NpO}_5, \text{cr}, 298.15 \text{ K}) = -(521.0 \pm 6.3) \text{ J} \cdot \text{K}^{-1} \cdot \text{mol}^{-1}$, $\Delta_f G_m^{\circ}(\text{Na}_4\text{UO}_5, \text{cr}, 298.15 \text{ K}) = -(2301.7 \pm 2.9) \text{ kJ} \cdot \text{mol}^{-1}$ and $\Delta_f G_m^{\circ}(\text{Na}_4\text{NpO}_5, \text{cr}, 298.15 \text{ K}) = -(2159.7 \pm 6.0) \text{ kJ} \cdot \text{mol}^{-1}$.

1. Introduction

In the potential event of a breach of the stainless steel cladding in a Sodium-cooled Fast Reactor (SFR), the sodium metallic coolant could come into contact with the nuclear fuel. $(\text{U,Pu})\text{O}_2$ mixed oxide fuel is the preferred option for SFRs because of the long experience accumulated with the current second generation Light Water reactor systems in terms of fabrication, reactor operation, reprocessing, and risk assessment. The additional incorporation of minor actinides (Np,Am,Cm) into the fuel is moreover envisioned in the framework of the international Generation IV program so as to reduce the radiotoxic inventory of the fuel cycle and its long term impact [1,2]. One solution to reduce the amount of waste and its radiotoxicity is indeed to recover the long-lived isotopes from the spent fuel and re-irradiate them in a fast reactor to transmute them into radioactive elements with shorter half-lives [1,2]. In this respect, the development of the SFR concept has led to a considerable interest for the reaction products between sodium coolant and $(\text{U,Pu,Np})\text{O}_2$ nuclear fuel. A thorough

knowledge of their structural and thermodynamic properties is essential from a safety perspective.

The phases forming in the $(\text{Na} + \text{U} + \text{O})$, $(\text{Na} + \text{Np} + \text{O})$, and $(\text{Na} + \text{Pu} + \text{O})$ systems are numerous: tetravalent Na_2PuO_3 , pentavalent NaUO_3 , Na_3AnO_4 , Na_5PuO_5 , hexavalent Na_2UO_4 , Na_2NpO_4 , Na_4AnO_5 , $\text{Na}_2\text{An}_2\text{O}_7$, and heptavalent Na_5NpO_6 , Na_5PuO_6 ($\text{An} = \text{U}, \text{Np}, \text{Pu}$) [3–13]. The structural properties of the sodium uranium ternary oxides have been reviewed extensively [3–6,8]. Their thermodynamic functions are also fairly well established at $T = 298.15 \text{ K}$ [14,15]. Only the heat capacities, entropies, and Gibbs energies of Na_4UO_5 and $\beta\text{-Na}_2\text{UO}_4$ are missing. By contrast, there is little knowledge of the sodium neptunates and plutonates. Keller et al. [9,10,16], Pillon et al. [17,4], Kleykamp [18], Smith et al. [11,13], and Bykov et al. [12] have contributed to their structural characterization, but there is a real lack of thermodynamic information on these phases [15]. Only the enthalpies of formation at $T = 298.15 \text{ K}$ of $\alpha\text{-Na}_2\text{NpO}_4$, $\beta\text{-Na}_2\text{NpO}_4$, Na_4NpO_5 , and $\text{Na}_2\text{Np}_2\text{O}_7$ have been measured experimentally using solution calorimetry [19,20,15] and Knudsen effusion mass spectrometry [21]. To complete the data on the $(\text{Na} + \text{U} + \text{O})$ and $(\text{Na} + \text{Np} + \text{O})$ systems, we report for the first time low temperature heat capacity measurements on Na_4UO_5 and Na_4NpO_5 and the determination of their heat capacities, entropies and Gibbs energies at $T = 298.15 \text{ K}$.

2. Experimental methods

2.1. Sample preparation and characterization

The Na₄UO₅ material was kindly provided by NRG (Nuclear Research & Consultancy Group, Petten, The Netherlands). The sample as received was furthermore sintered at $T = 923$ K under oxygen flow for 12 h to produce a compact material suited for the measurements.

Na₄NpO₅ was synthesized under oxygen flow by reaction at $T = 1100$ K between accurately weighted samples of neptunium dioxide (²³⁷NpO₂ from ORNL, Oak Ridge National Laboratory) and sodium carbonate (Na₂CO₃ 99.95%, Sigma). The total heating time amounted to 70 h, with intermediate regrinding steps. The purity of the samples was examined by X-ray diffraction at room temperature and ICP-MS analysis.

The X-ray diffraction measurements were carried out using a Bruker D8 X-ray diffractometer mounted in the Bragg–Brentano configuration with a curved Ge monochromator (111), a ceramic copper tube (40 kV, 40 mA), and equipped with a LinxEye position sensitive detector. The data were collected at room temperature, i. e. 300(5) K, by step scanning in the angle range $10^\circ \leq 2\theta \leq 120^\circ$, with an integration time of about 8 h, a count step of $0.02^\circ (2\theta)$, and a dwell of 5 s/step. Structural analysis was performed by the Rietveld method with the Fullprof2k suite [22].

Na₄UO₅ and Na₄NpO₅ are isostructural and crystallize in the tetragonal space group $I4/m (Z = 2)$ [7,13]. The lattice parameters found in the present work, $a = 0.7549(3)$ nm, $c = 0.4637(3)$ nm for Na₄UO₅ (Vol. = $0.2643(2)$ nm³ and $\rho = 5.152(4)$ g · cm⁻³), and $a = 0.7533(3)$ nm, $c = 0.4615(3)$ nm for Na₄NpO₅ (Vol. = $0.2619(2)$ nm³ and $\rho = 5.199(4)$ g · cm⁻³), respectively, are in very good agreement with the values reported in the literature [7,13]. Some very minor secondary phases of α -Na₂UO₄ and α -Na₂NpO₄ were detected with X-rays and quantified using the Rietveld method and ICP-MS analysis. According to our Rietveld refinement, the Na₄UO₅ batch was pure at 98.4 wt% with 1.6 wt% α -Na₂UO₄ impurity, corresponding to the composition Na_{3.962}UO_{4.981}. The ICP-MS analysis yielded a sodium to uranium ratio of (3.963 ± 0.016) at/at¹ in very good agreement with the latter quantification. The Na₄NpO₅ batch was pure at 99.5 wt% with 0.5 wt% α -Na₂NpO₄ impurity, corresponding to the composition Na_{3.988}NpO_{4.982}. The ICP-MS analysis yielded a sodium to neptunium ratio of (4.006 ± 0.048) at/at¹, also in good agreement with the quantification using X-rays.

2.2. Heat capacity measurements

Low temperature heat capacity measurements were performed in the temperature ranges (1.9 to 288.7) K and (2.4 to 292.2) K for Na₄UO₅ and Na₄NpO₅, respectively, using a PPMS (Physical Property Measurement System, Quantum Design) instrument in the absence of a magnetic field. This technique is based on a thermal relaxation method, which was critically assessed by Lashley et al. [23]. The measurements were carried out on pellets of 28.90(5) mg of Na₄UO₅ and 21.07(5) mg of Na₄NpO₅ materials encapsulated in Stycast 2850 FT, and the heat capacity contribution of the Stycast was subtracted from the recorded data. A more detailed description of the experimental procedure, which is particularly well adapted to the study of radioactive materials, was given in [24]. The contribution of the sample platform, wires, and grease was also deduced by a separate measurement of an addenda curve. The collected data for Na₄UO₅ and Na₄NpO₅ were finally corrected for 1.6 wt% and 0.5 wt% impurities of α -Na₂UO₄ and α -

Na₂NpO₄, respectively, which were measured by Osborne et al. [25] and Smith et al. [26].

Considering the accuracy of the PPMS instrument as estimated by Lashley et al. [23], the reproducibility of the measurements, and the error introduced by the encapsulation procedure in Stycast of these radioactive materials [24], the final uncertainty was estimated at about (1 to 2)% in the middle range of acquisition $T = (10$ to 100) K, and reaching about 3% at the lowest temperatures and near room temperature. The use of Stycast is the main contributor to the combined standard uncertainties on the heat capacities and entropies quoted hereafter. The uncertainties introduced by the presence of impurities are moreover within the uncertainty range of the method.

3. Results

The experimental heat capacity data collected for both samples in the absence of a magnetic field are shown in figure 1 and 2, and listed in table 8 and 9, respectively. As the temperature approaches 298.15 K, the specific heat reaches in both cases values that are about $30 \text{ J} \cdot \text{K}^{-1} \cdot \text{mol}^{-1}$ below the classical Dulong–Petit limit ($C_{\text{lat}} = 30R \approx 249 \text{ J} \cdot \text{K}^{-1} \cdot \text{mol}^{-1}$ for the ten atoms in the formula unit).

The heat capacity of Na₄UO₅ increases smoothly with temperature. Interestingly, the low-temperature heat capacity of Na₄NpO₅ shows a broad anomaly between $T = (3$ and 15) K with a maximum at about $T = 7$ K. This anomaly was found to be slightly shifted to lower temperatures when a magnetic field is applied as reported in our previous work [13]. The hypothesis of a magnetic ordering transition at about $T = 7$ K was ruled out based on our Mössbauer spectroscopy and magnetic susceptibility results. Instead, this feature was interpreted as a Schottky-type anomaly associated with low-lying electronic energy levels. Its entropy contribution was moreover estimated as $4.57 \text{ J} \cdot \text{K}^{-1} \cdot \text{mol}^{-1}$ after subtraction of the lattice contribution approximated with that of Na₄UO₅ [13]. We refer the reader to [13] for further details on this particular feature, and derivation of its associated entropy contribution.

In the present work, the thermodynamic functions of Na₄UO₅ and Na₄NpO₅ were derived at $T = 298.15$ K by fitting the experimental data to theoretical functions below $T = (20.0$ and 4.3) K [27], respectively, and a combination of Debye and Einstein heat capacity functions [28–30] from $T = (20.0$ to 288.7) K and $T = (23.2$ to 292.2) K, respectively. In addition, the Schottky anomaly observed for the neptunium compound was fitted between $T = (4.3$ and 23.2) K with a series of cubic spline polynomial functions. The fitted data are shown with solid lines in Figs. 1–3.

The heat capacity values at $T = 298.15$ K were obtained by extrapolation, yielding $C_{\text{p,m}}^{\circ}(\text{Na}_4\text{UO}_5, \text{cr}, 298.15 \text{ K}) = (220.6 \pm 6.7)^2 \text{ J} \cdot \text{K}^{-1} \cdot \text{mol}^{-1}$ and $C_{\text{p,m}}^{\circ}(\text{Na}_4\text{NpO}_5, \text{cr}, 298.15 \text{ K}) = (219.0 \pm 6.6)^3 \text{ J} \cdot \text{K}^{-1} \cdot \text{mol}^{-1}$, respectively. The experimental standard entropies at $T = 298.15$ K were determined by numerical integration of $(C_{\text{p,m}}/T) = f(T)$ using the aforementioned fitted functions, yielding $S_{\text{m}}^{\circ}(\text{Na}_4\text{UO}_5, \text{cr}, 298.15 \text{ K}) = (247.5 \pm 6.2) \text{ J} \cdot \text{K}^{-1} \cdot \text{mol}^{-1}$ and $S_{\text{m}}^{\circ}(\text{Na}_4 \text{ NpO}_5, \text{cr}, 298.15 \text{ K}) = (247.5 \pm 6.2) \text{ J} \cdot \text{K}^{-1} \cdot \text{mol}^{-1}$, respectively. Finally, standard thermodynamic functions were calculated at selected temperatures between (0 and 300) K and are listed in tables 10 and 11.

² The encapsulation procedure in Stycast is the main contributor (3%) to the quoted combined standard uncertainty. The errors associated with the Debye and Einstein fit (0.4%) and impurity contamination (0.4%) contribute very little to the final uncertainty.

³ The encapsulation procedure in Stycast is the main contributor (3%) to the quoted combined standard uncertainty. The errors associated with the Debye and Einstein fit (0.4%) and impurity contamination (0.1%) contribute very little to the final uncertainty.

¹ The uncertainty is an expanded uncertainty $U = k \cdot u_c$ where u_c is the combined standard uncertainty estimated following the ISO/BIPM Guide to the Expression of Uncertainty in Measurement. The coverage factor is $k = 2$.

4. Discussion

The heat capacity at constant volume, $C_{V,m}$, is given by the sum of the lattice vibrations, electronic, and magnetic contributions [31]. The relation between the heat capacity at constant pressure measured experimentally, $C_{p,m}$, and the heat capacity at constant volume, $C_{V,m}$, involves the isobaric thermal expansivity and isothermal compressibility of the material. At very low temperatures, the thermal expansivity is negligible, so that $C_{p,m} \approx C_{V,m}$.

4.1. Fitting of the lattice contribution above $T = 20$ K.

The lattice contribution dominates at temperatures above about $T = 20$ K, and can be modeled using a combination of Debye and Einstein functions, as written in Eq. (1). Two Einstein functions were needed in the present work to fit the data. Fitting with a single Einstein function was attempted, but could not reproduce accurately the high temperature region.

$$C_{p,m} = n_D D(\theta_D) + n_{E1} E(\theta_{E1}) + n_{E2} E(\theta_{E2}). \quad (1)$$

Here R is the universal gas constant equal to $8.3144621 \text{ J} \cdot \text{K}^{-1} \cdot \text{mol}^{-1}$, $D(\theta_D)$, $E(\theta_{E1})$, and $E(\theta_{E2})$ are the Debye, low and high temperature Einstein functions, respectively, as written in Eqs. (2) and (3). θ_D , θ_{E1} , and θ_{E2} are the characteristic Debye and Einstein temperatures. n_D , n_{E1} , and n_{E2} are adjustable parameters, whose sum ($n_D + n_{E1} + n_{E2}$) should be approximately equal to the number of atoms in the formula unit (i.e., 10 in this case).

Np–O(1)	2	2.30(1)
Np–O(2)	4	2.09(1)
Na–O(1)	1	2.40(1)
Na–O(2)	2	2.32(1)
Na–O(2)	1	2.48(1)
Na–O(2)	1	2.36(1)
Na–O(2)	1	2.66(1)

$$D(\theta_D) = 9R \left(\frac{1}{x}\right)^3 \int_0^x \frac{\exp(x)x^4}{[\exp(x) - 1]^2} \cdot dx, \quad x = \frac{\theta_D}{T}, \quad (2)$$

$$E(\theta_E) = 3Rx^2 \frac{\exp(x)}{[\exp(x) - 1]^2}, \quad x = \frac{\theta_E}{T}. \quad (3)$$

The fitted parameters obtained for Na₄UO₅ and Na₄Np₅ in the temperature regions (20.0 to 288.7) K and (23.2 to 292.2) K, respectively, are listed in table 4. The sum ($n_D + n_{E1} + n_{E2}$) is very close to 10. The Debye and Einstein temperatures are found systematically higher for the uranium compound, suggesting stronger bonding between the uranium cation and surrounding oxygen ions. The reverse behaviour would be expected, however, considering the respective bond lengths in the UO₆ [7] and NpO₆ octahedra [13], and ionic radii of the U⁶⁺ (0.73 Å) and Np⁶⁺ (0.72 Å) cations according to Shannon's tabulated data [32]. This result can be related to the fact that the experimental curves cross around $T = 35$ K, as seen in figure 3, and could be the effect of the 5f valence electrons since these compounds show different electronic configurations, namely [Rn]5f⁰ for Na₄UO₅ and [Rn]5f¹ for Na₄NpO₅. An alternative explanation would be the interplay between force constant and atomic mass [33]. However, considering the uncertainty of the method, and especially of the encapsulation procedure in Stycast, it is not possible to definitively assign this feature to a physical phenomenon. Calculations of the phonon density of states and of the vibration modes would be required to conclude.

The root mean square deviation (RMS) of the fits are rather high, despite a good general agreement with the experimental data. Indeed, the deviation from the experimental results remains below 0.4% over the temperature range (20 to 292) K, as shown in figure 4. The RMS discrepancy can be related to the uncertainty on our experimental results, which increases towards high temperatures, mainly due to the correction for the Stycast contribution.

4.2. Fitting below $T = 20$ K.

At very low temperatures ($T < 20$ K), the phonon contribution is well-represented using an harmonic-lattice model [27], as expressed by Eq. (4), where the number of required terms augments with the high temperature limit of the fit:

$$C_{latt} = \sum B_n T^n, \quad \text{where } n = 3, 5, 7, 9 \dots \quad (4)$$

The electronic contribution of the conduction electrons at the Fermi surface are represented with a linear term γT [34]. The electronic specific heat is zero for insulating materials such as Na₄UO₅ and Na₄NpO₅ (orange and lime green, respectively). However, recent studies have revealed that a linear term could nevertheless occur due to departure from stoichiometry, oxygen vacancies or defects within the material [27]. α -FeOOH [27], Fe₂P₂O₇ [35], and Sr₂TiSi₂O₈ [33] are example of such materials.

The heat capacity of Na₄UO₅ was fitted with the harmonic model using four terms to cover the rather large temperature range of the fit (1.9 to 20.0) K. The corresponding coefficients are listed in table 4. A simple two terms harmonic model was sufficient to cover the temperature range (2.4 to 4.3) K in the case of Na₄NpO₅. However, the addition of a linear δT term also appeared necessary to describe the experimental curve. The broad Schottly anomaly was fitted between $T = (4.3 \text{ and } 23.2)$ K using a series of cubic spline polynomials.

The need for a linear δT term to fit the Na₄NpO₅ data in the temperature range (2.4 to 4.3) K suggests the presence of a non negligible amount of oxygen vacancies or defects within the material [27]. This observation can be related to the particular peak profile shape observed in the X-ray diffraction pattern as detailed in Appendix A. The Bragg reflections indeed show an asymmetric profile in opposite directions for successive hkl reflections, which is particularly pronounced at low angles, as detailed in [13]. This feature was interpreted in our previous work as a slight heterogeneity within the material which creates stresses. In fact, the Rietveld refinement and the description of the peak profile shape can be improved by introducing a second tetragonal phase with slightly larger cell volume, which concurs with the hypothesis of the formation of oxygen vacancies or defects (see Appendix A). A departure from stoichiometry is unlikely, however, as the Mössbauer data showed no traces of pentavalent neptunium in this material [13]. Instead, it is suggested that oxygen Frenkel pairs might occur. The δT term is much larger than reported in the literature for this type of defects, however [27,33], which is rather puzzling. Self-heating effects coming from the radioactive decay of ²³⁷Np were considered, but appeared negligible. The corresponding contribution amounts to no more than 0.5% at $T = 2.5$ K and 0.04% at $T = 10$ K of the signal. The physical interpretation of this phenomenon could therefore be more intricate.

4.3. Modelling the Schottky-type anomaly

The neptunium cation in Na₄NpO₅ is hexavalent, as confirmed by Mössbauer spectroscopy [13], and shows therefore a [Rn]5f¹ electronic configuration. The Np ion in this structure is therefore a Kramers ion with a ²F_{5/2} ground state manifold and ²F_{7/2} first excited state arising from spin-orbit coupling. The ²F_{5/2} ground state has a degeneracy of $(2J + 1) = 6$, and is subsequently split into three Kramers doublets (Γ_7 ground state, and Γ_7^t, Γ_6^t excited states) by the crystal field effect in the tetragonally distorted (D_{4h}) symmetry [13]. Our previous studies have shown that Na₄NpO₅ probably shows two low-lying states having the same degeneracy and separated by about 14 cm⁻¹ [13]. It was therefore attempted in the present work to fit the anomaly in the heat capacity data using a simple two levels Schottky function as written in Eq. (5) [34]:

$$C_{Schottky} = R \left(\frac{\theta_S}{T}\right)^2 \frac{g_0}{g_1} \frac{\exp\left(\frac{\theta_S}{T}\right)}{\left(1 + \frac{g_0}{g_1} \exp\left(\frac{\theta_S}{T}\right)\right)^2}, \quad (5)$$

TABLE 8

Experimental heat capacity data^a for Na₄UO₅ measured at pressure $p = 1.233 \text{ mPa}$ ^b. The reported data were corrected for 1.6 wt% $\alpha\text{-Na}_2\text{UO}_4$ impurity [25]. R is the ideal gas constant equal to $8.3144621 \text{ J} \cdot \text{K}^{-1} \cdot \text{mol}^{-1}$.

^a The standard uncertainties u on the temperature are: $u(T) = 0.01$ K for $1.9 < T/K < 20$, $u(T) = 0.02$ K for $20 < T/K < 100$, $u(T) = 0.05$ K for $100 < T/K < 300$. The combined relative standard uncertainties on the values of the heat capacities are determined to be $u_r(C_{p,m}) = 0.03$ for $T/K < 10$, $u_r(C_{p,m}) = 0.01$ for $10 < T/K < 70$, $u_r(C_{p,m}) = 0.02$ for $70 < T/K < 100$, $u_r(C_{p,m}) = 0.025$ for $100 < T/K < 150$, and $u_r(C_{p,m}) = 0.03$ for $T/K > 150$.

^b The standard uncertainty u on the pressure is: $u(p) = 0.009$ mPa.

where θ_5 is the spacing between the two low-lying electronic levels expressed in K, g_0 and g_1 their respective degeneracy ($g_0/g_1 = 1$ in this case). θ_5 is related to the energy separation ε_1 between the two levels via the formula $\theta_5 = \varepsilon_1/k_B$, where k_B is Boltzmann constant equal to $1.3806488 \cdot 10^{-23} J \cdot K^{-1}$.

The heat capacity of Na_4NpO_5 was thereafter represented using the aforementioned function together with a three terms harmonic model as written in Eq. (6). The corresponding coefficients are listed in table 4.

$$C_{p,m}(Na_4NpO_5, cr, T) = B_3T^3 + B_5T^5 + B_7T^7 + \alpha_5 C_{Schottky}, \quad (6)$$

where α_5 is a scaling factor adjusting the amplitude of the theoretical Schottky function to the one actually observed in the experiment.

The maximum temperature of the broad anomaly is fairly well described with such model as shown in figure 5. The spacing between the two low-lying electronic levels is at about $T = (20.1$ to $22.9)$ K, which corresponds to an energy separation of $(14$ to $15.9) \text{ cm}^{-1}$, in good agreement with our previous study [13]. The combination of the simple two levels Schottky function and harmonic model is not sufficient, however, to describe adequately both the width and intensity of the data below $T = 6.5$ K. The experimental $(C_{p,m}/T)$ curve saturates at about $275 J \cdot K^{-2} \cdot mol^{-1}$

TABLE 9

Experimental heat capacity data^a for Na_4NpO_5 measured at pressure $p = 1.233$ mPa^b. The reported data were corrected for 0.5 wt% α - Na_2NpO_4 impurity [26]. R is the ideal gas constant equal to $8.3144621 J \cdot K^{-1} \cdot mol^{-1}$.

^a The standard uncertainties u on the temperature are: $u(T) = 0.01$ K for $1.9 < T/K < 20$, $u(T) = 0.02$ K for $20 < T/K < 100$, $u(T) = 0.05$ K for $100 < T/K < 300$. The combined relative standard uncertainties on the values of the heat capacities are determined to be $u_r(C_{p,m}) = 0.03$ for $T/K < 10$, $u_r(C_{p,m}) = 0.01$ for $10 < T/K < 70$, $u_r(C_{p,m}) = 0.02$ for $70 < T/K < 100$, $u_r(C_{p,m}) = 0.025$ for $100 < T/K < 150$, and $u_r(C_{p,m}) = 0.03$ for $T/K > 150$.

^b The standard uncertainty u on the pressure is: $u(p) = 0.009$ mPa.

FIGURE 3. $C_{p,m}/T$ for Na_4UO_5 (\circ) and Na_4NpO_5 (\blacktriangle) measured in zero magnetic field, and fit to the data (plain and dotted lines).

instead of going to zero when reaching $T = 0$ K, probably due to the presence of defects within the material as detailed previously. This effect makes it more difficult to describe the anomaly with a theoretical Schottky function. Moreover, the associated entropy is less ($\alpha_{S1} = 0.85$, $\alpha_{S2} = 0.73$) than predicted by theory ($\Delta S_{\text{Schottky}} = R \ln 2 = 5.76 \text{ J} \cdot \text{K}^{-1} \cdot \text{mol}^{-1}$), which also renders the fitting procedure more intricate. We have therefore preferred in the present work to fit the broad Schottky anomaly with a series of cubic spline polynomials so as to derive the thermodynamic functions between $T = (0 \text{ and } 300) \text{ K}$.

4.4. Derivation of thermodynamic functions

The empirical Neumann–Kopp (NK) rule, which suggests that the heat capacity of a solid is the sum of the heat capacity of its constituent chemical components, is usually a good approximation for the estimation of the specific heat at $T = 298.15 \text{ K}$ [36]. From the data of UO_3 [37] and Na_2O [38], the heat capacity of Na_4UO_5 can be estimated as $219.9 \text{ J} \cdot \text{K}^{-1} \cdot \text{mol}^{-1}$, in very good agreement with our

^a The relative combined standard uncertainties in the values of the fitted heat capacities are determined from the experimental and fitted uncertainties to be $u_r(C_{p,m}) = 0.031$ for $T/K < 10$, $u_r(C_{p,m}) = 0.011$ for $10 < T/K < 70$, $u_r(C_{p,m}) = 0.021$ for $70 < T/K < 100$, $u_r(C_{p,m}) = 0.026$ for $100 < T/K < 150$, and $u_r(C_{p,m}) = 0.031$ for $T/K > 150$. The standard uncertainty on the pressure is $u(p) = 5$ kPa.

^a The combined standard uncertainties in the values of the fitted heat capacities are determined from the experimental and fitted uncertainties to be $u_r(C_{p,m}) = 0.03$ for $T/K < 10$, $u_r(C_{p,m}) = 0.011$ for $10 < T/K < 70$, $u_r(C_{p,m}) = 0.02$ for $70 < T/K < 100$, $u_r(C_{p,m}) = 0.025$ for $100 < T/K < 150$, and $u_r(C_{p,m}) = 0.03$ for $T/K > 150$. The standard uncertainty on the pressure is $u(p) = 5$ kPa.

FIGURE 4. Deviation of the fitting equations from the experimental data for Na_4UO_5 (○) and Na_4NpO_5 (★).

FIGURE 5. $C_{p,m}/T$ for Na_4NpO_5 (○) measured in zero magnetic field below $T = 30$ K, and fitting using a combination of a Schottky function (dotted line) and harmonic lattice contribution (short dotted line). The configuration (1) corresponds to $\varepsilon_1 = 14$ cm^{-1} and $\alpha_5 = 0.85$. The configuration (2) corresponds to $\varepsilon_1 = 15.9$ cm^{-1} and $\alpha_5 = 0.73$.

experimental results. The sum of the heat capacities of NpO_2 [37], Na_2O [38], and Na_2O_2 [38] gives $224.6 J \cdot K^{-1} \cdot mol^{-1}$ for Na_4NpO_5 . The comparison is not ideal, however, as the neptunium adopts different oxidation states in Na_4NpO_5 and NpO_2 , namely (VI) and (IV),

respectively. The local structural environment around the neptunium cation is also different (6-fold coordination in Na_4NpO_5 , but 8-fold coordination in NpO_2). A more appropriate comparison is with the sum of α - Na_2NpO_4 [26] and Na_2O [38], which amounts to $221.0 J \cdot K^{-1} \cdot mol^{-1}$, in very good agreement with the experiment.

Combining our newly determined values of the standard entropies with the ones for sodium [39,15], uranium [37], neptunium [37], and oxygen [39], the standard entropies of formation of Na_4UO_5 and Na_4NpO_5 were estimated as $\Delta_f S_m^o(Na_4UO_5, cr, 298.15 K) = -(520.8 \pm 6.3) J \cdot K^{-1} \cdot mol^{-1}$ and $\Delta_f S_m^o(Na_4NpO_5, cr, 298.15 K) = -(521.0 \pm 6.3) J \cdot K^{-1} \cdot mol^{-1}$, respectively.

The enthalpies of formation reported for those compounds at $T = 298.15 K$ [15] are listed in table 5. Using the aforementioned values for the standard entropies and enthalpies, the following standard Gibbs energies of formation were derived at $T = 298.15 K$: $\Delta_f G_m^o(Na_4UO_5, cr, 298.15 K) = -(2301.7 \pm 2.9) kJ \cdot mol^{-1}$ and $\Delta_f G_m^o(Na_4NpO_5, cr, 298.15 K) = -(2159.7 \pm 6.0) kJ \cdot mol^{-1}$, respectively.

Finally, considering the hypothetical dissociation reaction (7) for Na_4MO_5 ($M = U, Np$), the dissociation Gibbs energy is expressed by relation (8), where Na_4MO_5 and MO_2^{2+} have the same electronic state.

$$\begin{aligned} \Delta_f G_m^o(T) = & 4 \Delta_f G_m^o(Na^+, aq, T) + 3 \Delta_f G_m^o(H_2O, l, T), \\ & - 6 \Delta_f G_m^o(H^+, aq, T), \\ & + \Delta_f G_m^o(MO_2^{2+}, aq, T) - \Delta_f G_m^o(Na_4MO_5, cr, T), \quad (8) \\ = & f(T) + \Delta_f G_m^o(MO_2^{2+}, aq, T) - \Delta_f G_m^o(Na_4MO_5, cr, T). \quad (9) \end{aligned}$$

The Gibbs energies of formation of the species Na_4MO_5 and MO_2^{2+} are the only terms that differ in between the expressions of the dissociation energies of the sodium uranate and neptunate compounds. The other terms can be expressed as $f(T)$, independent of the actinide cation. The Gibbs energies of formation of the uranium and neptunium aqua ions were reported at $T = 298.15 K$ as $-(952.551 \pm 1.747) kJ \cdot mol^{-1}$ and $-(795.939 \pm 5.615) kJ \cdot mol^{-1}$ [15], respectively. Using the latter values and those tabulated for $Na^+(aq)$, $H^+(aq)$, and $H_2O(l)$ [15], the Gibbs energies of dissociation are derived at $T = 298.15 K$ as $-(410.1 \pm 3.4) kJ \cdot mol^{-1}$ and $-(395.5 \pm 8.2) kJ \cdot mol^{-1}$ for Na_4UO_5 and Na_4NpO_5 , respectively. The sodium neptunate appears slightly more stable than the sodium uranate, even if the difference remains small considering the uncertainty ranges.

5. Conclusions

The heat capacities of Na_4UO_5 and Na_4NpO_5 have been measured over the temperature range (1.9 to 292) K using a

FIGURE 6. Zoom of the X-ray diffraction pattern of Na_4NpO_5 at low angles showing the asymmetric profile in opposite directions for successive hkl reflections, which is particularly pronounced at low angles. This is due to slight heterogeneity within the material which creates stresses. Figure taken from [13].

FIGURE 7. (a) Comparison between the observed (Y_{obs} , in red) and calculated (Y_{calc} , in black) X-ray diffraction patterns of Na_4NpO_5 . $Y_{obs} - Y_{calc}$, in blue, is the difference between the experimental and calculated intensities. The Bragg reflections' angular positions are marked in green. Measurement at $\lambda = \text{Cu} - \text{K}\alpha 1$. (b) The inset shows a zoom between 36.9 and 43.2°. Quantum Design PPMS calorimeter. The experimental data have been fitted using theoretical functions below $T = (20.0$ and $4.3)$ K, respectively, and a combination of one Debye and two Einstein functions above $T = (20.0$ and $23.2)$ K, respectively. The theoretical fitting required the use of a linear term for the neptunium compound, which could be related to the presence of a non negligible amount of defects, in good agreement with the peak profile shape of the corresponding X-ray diffraction pattern. A broad Schottky anomaly has also been observed between $T = (3$ and $15)$ K, which is associated with two low-lying electronic energy levels separated by about $(14$ to $16)$ cm^{-1} (see tables 1–3).

The fitting functions have been used to derive the heat capacities and entropies of both compounds at $T = 298.15$ K. Combining the data with the enthalpies of formation reported in the literature, the Gibbs energies of formation have finally been determined, and are listed in table 5. Comparing the Gibbs energy values, the sodium neptunate was found to be slightly more stable than its isostructural uranium analogue.

Acknowledgments

The authors would like to express their gratitude to D. Bouëxière for the collection of X-ray data, and to the Analytical Services of the Institute for Transuranium Elements for performing the ICP-MS analysis. They also thank the 7th Framework Program of the European Commission, and the Joint Advanced Severe Accidents Modelling and Integration for Na-cooled neutron reactors (JASMIN) programme (N°295803 in FP7). ALS acknowledges the European Commission and the Ras al Khaimah Centre for Advanced Materials for funding her PhD studentship. ALS also thanks Prof. A. K. Cheetham from the Department of Materials Science and Metallurgy of the University of Cambridge for the fruitful discussions, and his strong and continuous support.

Appendix A

The X-ray diffraction pattern of the synthesized Na_4NpO_5 material showed Bragg reflections with an asymmetric peak profile shape in opposite directions for successive hkl reflections, as reported in our previous work [13]. This effect is particularly pronounced at low angles. figure 6, which is taken from [13], illustrates this feature between $2\theta = 36.2$ to 42.2° . This effect was related to slight heterogeneity within the material, which creates stresses [13].

The fitting of the low temperature heat capacity data reported herein at low temperatures ($T < 4.3$ K) required the addition of a linear term to describe the experimental curve. The existence of an electronic contribution is ruled out, however, as Na_4NpO_5 is a lime-green insulating material. But the work of [27] suggested that such a linear term could arise due to departure from stoichiometry, oxygen vacancies, or defects within an insulating material. It is therefore suggested that the Na_4NpO_5 material shows oxygen vacancies or defects.

It was subsequently attempted in the present work to introduce a second tetragonal phase, in space group $I4/m$, to improve the Rietveld refinement of the experimental X-ray diffraction data. The refinement was constrained, however, with respect to a number of parameters: both tetragonal phases were forced to adopt the same atomic positional, asymmetry, and peak shape η parameters. In fact, only the cell parameters were allowed to differ from one phase to the other. The corresponding refinement is shown in figure 7. As can be seen in the latter figure, this approach allows a much better description of the peak profile shape, which is also reflected in the value of the R_{wp} factor reduced to 11.2% (as opposed to 17.7% when performing the refinement with a single tetragonal phase [13]) (table 6). The refined bond lengths, listed in table 7, are very close to the ones reported previously [13].

The refined cell parameters are found as ($a = 0.7532(3)$ nm, $c = 0.4618(3)$ nm) and ($a = 0.7555(3)$ nm, $c = 0.4605(3)$ nm) for the first and second tetragonal phases, respectively, the corresponding weight fractions being 61.8 wt% and 38.2 wt%. This yields unit cell volumes of $0.2620(2)$ and $0.2628(2)$ nm^3 , respectively. The second phase showing a larger cell volume could correspond to the defect fraction of the material. Its rather large weight fraction (38.2 wt%) causes a similarly large linear δT contribution (~ 275 $\text{mJ} \cdot \text{K}^{-2} \cdot \text{mol}^{-1}$) below $T = 4.3$ K in the experimental heat capacity data.
