We present a microfluidic platform that allows undergoing different chemical operations in a nanoliter droplet starting from colloidal suspension of magnetic iron oxide (\(\gamma\)-Fe\(_2\)O\(_3\)) nanoparticles “NPs” (ferrofluid). These operations include: mixing, flocculation, magnetic decantation, colloidal redispersion, washing, surface functionalization, heating and colloidal assembly. To prove the platform capabilities, we produced fluorescent and magnetic nanoassemblies composed of fluorescent silica and magnetic NPs.

Due to their specific properties rising from their small dimensions, nanoparticles (NPs) are used in various applications such as catalysis, optics, electronics and biomedical diagnosis or nanomedicine.\(^1,2\) To extend even more the range of properties and applications of NPs, several nanomaterials can be combined into one single nanostructure to form a multifunctional nanohybrid. This can be accomplished by controlling the assembly of smaller nanostructures (building blocks) of various shapes and compositions to create complex and single nanoscale object, having different properties provided by each of the different nanomaterials.\(^3\)

In the context of nanoparticle synthesis and assembly, different microfluidic strategies had already been shown with a high level of synthesis control enabling the production of high quality nanostructures with single or multi-functionalities.\(^4,5\) Particularly, in materials science, droplet microfluidics has been identified as a powerful tool to control chemical reactions through their compartmentalisation inside individual droplets, where each droplet acts as a micro-reactor allowing reaction parallelisation, reduction of reagents volume and accurate mixing associated to an enhancement of mass and heat transfer compared with bulk reactions.\(^6\) Moreover, it is also possible to manipulate individually each droplet to perform complex operations such as splitting, merging, sorting that allow to combine different chemical reactions.\(^7,8\) Despite several convincing reports on the use of microfluidics for the elaboration of nanomaterials through chemical synthesis or self-assembly,\(^9-11\) there is still rooms for high impact studies relying on technology for complex workflow implementation at microfluidic scale. In particular, manipulations of magnetic nanoparticles in microfluidic systems are still limited to single step reactions\(^12\) or multistep continuous modifications\(^13\) when operations as extraction, washing or NP functionalisation are not required or performed out from the microfluidic devices by conventional approaches. This is mainly due to their nanoscale dimension which renders difficult their handling in confined condition, where low amount of NPs, or in other words low amount of paramagnetic materials, results in low magnetic force. In these states typical macroscale protocols cannot be directly exploited. Herein we provide for the first time an automated microfluidic platform capable of manipulating nanoliter droplets and performing multistep and automated sequences of operations on magnetic NPs. These operations include screening of colloidal interactions magnetic decantation, colloidal redispersion, washing, surface functionalization, heating and colloidal assembly. In order to illustrate the potential of this microfluidic technology we report the elaboration of fluorescent and magnetic nanoassemblies from fluorescent silica and magnetic NPs as building blocks. Nanohybrid structures with dual functionalities are very promising and have proven their potential in different biomedical contexts such as drug delivery, magnetic resonance imaging (MRI) and hyperthermia cancer treatment.\(^2,14\)

Figure 1a summarises the fully automated droplet-based microfluidic platform, which is able to generate droplets, control the liquid handling, the magnetic actuation, as well as the droplet temperature. It is composed of a syringe pump equipped with 250µL syringe (by SGE) and coupled with a pipetting robot (Nemesys and Rotaxys, by Cetoni GmbH) that allows the generation of trains of droplets starting from solutions collected in a standard microtiter plate. A PTFE capillary (inside/outside diameter of 300 µm/600 µm, by Sigma Aldrich) is used as a pipetting needle to aspirate alternatively the different reagent solutions and fluorinated oil (FC-40 by 3M) that is used as continuous phase. This module, which is inspired by the one presented by Chabert et al.\(^15\), offers the possibility to generate a deterministic and confined train of droplets in a range between 50 and 300Nl (see example in Figure 1b) with an error in volume of about 2%. In order to generate stable

Electronic Supplementary Information (ESI) available: [microfluidic droplets heater, TEM and magnetic characterisations of magnetic nanoparticles, phase diagram for trapping magnetic nanoparticles, TEM images of the building blocks, preparation of TEM grids and Movies captions]. See DOI: 10.1039/x0xx00000x
droplets, FC-40 is mixed with 2% (w/w) of a fluorinated surfactant (1H,1H,2H,2H-perfluorodecan-1-ol, by Fluorochem). Additionally, the microtiter plate is entirely covered with a small layer (about 2mm) of mineral light oil (Sigma Aldrich) to avoid the reagent evaporation. Since the syringe pump can work in both injections and withdrawal modes, droplets can be moved forward and backward in the capillary. This capability will be exploited for inducing a recirculation inside the droplet, which helps the internal mixing. Once the train of droplets is generated, droplets can be driven between the magnetic tweezers to achieve the manipulation of the magnetic NPs and through a homemade heater (see ESI, Figure S1), which allows the temperature control of the droplet. The magnetic tweezers consist of two sharp magnetic tips (AFK502 Imphy Alloys) facing each other across a capillary where the magnetic force is higher than the capillary force allowing to collect them in a cluster that can be extracted by driving them between the magnetic tweezers facing each other. Therefore it is possible to switch ON and OFF the droplet of ferrofluid manipulation and the homemade heater that can be easily tuned at the desired temperature.

Figure 1. a) Microfluidic setup for the generation of deterministic trains of droplets. Syringe pump synchronised with a pipetting robot generates the droplet from a microtiter plate, sucking water phase solutions and oil alternatively. These droplets are then driven between the magnetic tweezers (picture in the inset) for ferrofluid manipulation and the homemade heater that can be easily tuned at the desired temperature. b) Train of droplets for nanoassembling production: 1) 50nL of γ-Fe₂O₃ solution, 2) 50N of sodium citrate solution, 3) 200nL of acetone/water solution, 4) 2 drops of 200nL of milliQ water, 5) 50nL of 3-(N-Morpholino)propanesulfonic acid (MOPS) and 6) 200nL of silicato fluorescent NPs.

Based on these validations, we demonstrated the potential of the platform to perform series of complex synthesis workflows. In particular we focused on the elaboration of magnetic and fluorescent nanomaterials from maghemite (γ-Fe₂O₃) and silica NPs as building blocks. We have selected γ-Fe₂O₃ NPs of d₀=2-3 nm as the magnetic building block since NPs with this size are easier to manipulate using our tweezers and have proven their efficiency in different applications related to nanomedicine. The other building block is amine functionalised fluorescent silica NPs (RITC-SiO₂) (d=200±4 nm; ESI Figure S5) that have been synthesised according to the modified Stöber method using the Rhodamine B isothiocyanate (RITC, λₘₐₓ=555 nm) as a fluorescent dye. The amine functionalised silica NPs are stable at pH= 7 in 10⁻⁴ mol-L⁻¹ of 3-(N-Morpholino)propanesulfonic acid (MOPS) pH buffer and their zeta potential is ζ=±35mV.

To build our assembly through electrostatic interaction at pH=7 between the positively charged silica and the maghemite NPs, we

Brownian motion. In particular, in this case we noticed that the entire aqueous droplet is trapped, but no cluster formation and extraction are observed (see Movie 2, ESI). In fact, NPs experience two opposite forces: the magnetic force which tends to aggregate them and the colloidal force which keeps the suspension stable, resulting in a metastable system where the droplet is trapped at the magnetic tweezers (see paragraph 2 in ESI). Nevertheless, it is interesting to notice that even if it does not permit particle extraction, this effect can be advantageously exploited for merging two following droplets.

Size sorted cationic ferrofluids of maghemite (γ-Fe₂O₃) NPs suspended in nitric acid (pH= 2), with different diameters (d₀ between 5-9nm; see ESI, Figure S3 for more details) were synthesised according to our previous described methods. A phase diagram describing the efficiency of ferrofluid droplet trapping effect was build to report the influence of NPs diameter and iron concentration ([Fe]) at constant oil flow rate (Q=0.02μL·s⁻¹) (see ESI, Figure S4). Q was chosen in order to be able to trap also the droplet of ferrofluid with smaller NPs at lower concentration of iron. Since the magnetic force is proportional to the quantity of magnetic material, as expected bigger and higher concentrated NPs are more suitable for the droplet trapping. For example fixing [Fe]=0.3 mol·L⁻¹, only droplet containing NPs having d₀≥7nm can be trapped.

In order to perform complex ferrofluid manipulation, it is necessary to be able to extract the NPs from the ferrofluid. This can be achieved increasing the magnetic field to overcome the colloidal force and generate a cluster, as described for micrometric particles, or destabilizing the colloidal suspension. Considering the difficulties to generate high magnetic fields using electromagnets, the latter solution was found to be simpler and more straightforward to implement experimentally. In particular, this was achieved by merging the droplet of ferrofluid with a droplet of acetone, which increases the solvent permittivity leading to NPs flocculation. At this point, NPs are not stable in the solutions, they aggregate quickly and accumulate at the tweezers forming a cluster that can be extracted from the initial droplet (see Movie 3, ESI) and released in any following droplet or washed with subsequent droplets.
decided to coat their surface with citrate molecules since maghemite NPs are not stable at this pH. The role of this coating is to ensure their colloidal stability due to carboxylate functional groups on their surface, which also guarantee a strong interaction with positively charged silica NPs.

Therefore, the workflow necessary for reaching the final assembly, which is completely performed in droplets, is illustrated in Figure 2a. At first, the train of droplets sketched in Figure 1b is generated: 1) 50nL droplet of $\gamma$-Fe$_2$O$_3$ solution ($d_{p}=9$nm, $[\gamma$-Fe$_2$O$_3]=8.2 \times 10^{18}$NPs-L$^{-1}$ or $[\text{Fe}]=0.44$ mol-L$^{-1}$; 2) 50nL of 0.027mol L$^{-1}$ trisodium citrate solution giving a molar ratio Fe/citrate=16; 3) 200nL of an acetone/water mixture (50/50 v/v); 4) two water droplets of 200nL each; 5) 50nL of 10$^{-3}$ mol/L MOPS pH buffer solution ($\text{pH}=7$) and 6) 200nL of silica fluorescent NPs ($d=200$ nm, [RITC-SiO$_2$]= 1.88 x 10$^{-5}$ NPs-L$^{-1}$). Based on the trapping mechanism previously described, the droplet containing $\gamma$-Fe$_2$O$_3$ is trapped at the tweezers and merged with the following droplet containing trisodium citrate (step 1, Figure 2b-g) to perform the NPs citration. The addition of trisodium citrate solution induced nanoparticle destabilisation and precipitation in the droplet (see Movie 4 ESI) due to the high ionic strength. To accelerate diffusion and grafting of citrate molecules on the surface of magnetic NPs, the resulting mixture in the droplet was flown in the microfluidic heater introduced above and heated at 60°C for 5 minutes (step 2 in Figure 2). After this step, the resulting suspension of $\gamma$-Fe$_2$O$_3$ became optically homogeneous indicating uniform dispersion of stabilized citrate functionalised magnetic NPs in the droplet. Since the sodium citrate is in excess, we expected that the reaction efficiency is 100% and all the NPs resulted functionalized. To remove the excess of citrate molecules, the droplet from step 2 was magnetically trapped again and merged with a droplet containing the mixture of acetone/water, while keeping the magnetic field and the oil flow ON (step 3, Figure 2h-m, Movie 3 ESI). As previously introduced, thanks to the acetone, we could extract the citrated magnetic NPs from the excess of citrate presented in the droplet solution. In the step 4 (figure 2n-s), the NPs cluster was washed with two water droplets, and finally released in the MOPS solution. During washing, the flocculated NPs through which the water droplets flowed were kept trapped at the tweezers. Figure 2n-p and Movie 5 in ESI show how the cluster becomes larger when the water droplets pass through, evidencing slight redispersion of the NPs. Additionally some $\gamma$-Fe$_2$O$_3$ NPs are lost in the washing droplet; evaluating the grey levels of the Movie 5, we estimate that this quantity is about the 10% of the total cluster of NPs. Then, when the MOPS solution was mixed with the magnetic NPs (Figure 2q-s and Movie 6 ESI), the resulting droplet was released from the tweezers and flown for 1 minute in the capillary to obtain a better mixing. At this stage, no NPs sedimentation was observed even after 1 hour suggesting the efficient stability of $\gamma$-Fe$_2$O$_3$-citrated NPs in MOPS. Finally, the droplet containing the citrated magnetic NPs dispersed in MOPS was trapped at the tweezers and merged with a droplet loaded with the RITC-SiO$_2$ fluorescent NPs in order to induce the assembly of RITC-SiO$_2$-$\gamma$-Fe$_2$O$_3$ nanohybrids through electrostatic interactions. As presented in the previous case, mixing was done flowing the resulting droplet in the capillary for 1 minute in order to benefit from the internal recirculation flows.

**Optical fluorescence microscopy** was used to confirm the successful formation of RITC-SiO$_2$-$\gamma$-Fe$_2$O$_3$ assemblies in the nanodroplets. As shown in Figure 3a when the magnetic field (B) is OFF, the nanoassemblies obtained in the droplet are randomly distributed due to Brownian motion; while in presence of a permanent magnetic field (Figure 3b), the fluorescent homogenized nanoparticles lined up (white arrow) along the magnetic field direction (see also Movie 7, ESI) to form chainlike structures due to the attractive interaction between the magnetic moments. Additionally, applying a magnetic field gradient to the RITC-SiO$_2$-$\gamma$-Fe$_2$O$_3$ assemblies confined in droplet by a permanent magnet, we observed that they tend to agglomerate close to it (see Movie 8,
We thank Dr. Daniel Lévy and Aurélie Di Cicco for their help in TEM measurements. This work was supported in part by the Digidiag project (ANR) from the French government, the ARC foundation.
