In this study, betaine-type polyampholytes (polycarbobetaines, PCBets) are investigated as complexing agents of metal ions. Because PCBets are pH-sensitive due to the presence of amine and carboxylic acid groups, the complexation of copper was monitored at various pH values (from 3 to 6) by UV-vis spectroscopy and/or electrochemical measurements. The results obtained for the complexation of copper were greatly enhanced as the pH increased and reached $264 \pm 11 \text{ mg g}^{-1}$ at pH=6. This maximum adsorption capacity rivals the recent results obtained for molecules of environmental interest, such as chitosan. The selectivity of the target PCBets for copper was indicated in the presence of nickel and/or cobalt and partially accounts for the interest in this material and demonstrated the relevance of using PCBet in environmental applications (such as metal recovery from wastes/wastewaters or environmental sensors). The efficiency of copper adsorption was maintained over 5 cycles of PCBet reuse ($91 \pm 4 \%$).

Keywords: polycarbobetaines, copper, complexation, isotherms, selectivity, reusable
1. Introduction

Currently, metals are highly studied in environmental management because of their depletion as resources and because of the increasingly common cases of pollution [1]. Thus, their recovery and valorization are key themes of recent scientific studies concerning the environment. Copper ions are produced as waste in various chemical industries, such as smelting, mining, printed circuit board manufacturing, electroplating, wire drawing, copper polishing, and paint manufacturing [2]. Various techniques, such as chemical precipitation, coagulation, solvent extraction, ultra-filtration, biological systems, electrolytic processes, reverse osmosis, oxidation with ozone/hydrogen peroxide, membrane filtration, ion exchange, photocatalytic degradation and adsorption, have been developed for the removal of metal contaminants from waste [3]. Among these techniques, precipitation appears as the most attractive, primarily because of its economical operation. However, one disadvantage exists when treating multi-element samples because all metals are typically precipitated together in sludge without any possibility to valorize them. Selective precipitating agents, such as dithiocarbamate and their ramifications, 2,4,6-trimercapto-1,3,5-triazine, or dipropyl dithiophosphate, have been studied, but their high cost inhibits their use for different industrial applications [4]. Adsorption is also a well-studied and efficient technique that has been considered more often for metal ion selective treatment [5]. Low-cost natural and synthetic adsorbents have already demonstrated good performances for copper removal from wastewaters [6-9]. Hydrogels are also considered for these applications [10]. However, these techniques are less cost-effective compared with precipitation when considering the clogging/unclogging operational problems in the technology.

This research is devoted to the study of polybetaines as metal ion precipitating agents. Polybetaines are specific polyampholytes that possess anionic and cationic groups on the same monomer unit. Among polybetaines, polysulfobetaines, polycarbobetaines and
polyphosphobetaines are prominent [11]. This study investigates polycarbobetaines (PCBets) and their interactions with copper to design chemical processes for copper valorization. Cross-linked PCBet hydrogels have been tested for copper adsorption [2, 12, 13]; however, no literature exists about water-soluble PCBets for similar applications [14], although water-soluble polymers have been suggested to enhance filtration systems [15-17].

2. Theoretical background

The interactions of water-soluble polymers with metal ions are treated as surface phenomena as previously reported [18]. The most appropriate method for assessing sorption capacity is the derivation of a whole sorption isotherm [19]. Over the years, a wide variety of equilibrium isotherm models (Langmuir, Freundlich, Brunauer–Emmett–Teller, Redlich-Peterson, Dubinin–Radushkevich, Temkin, Toth, Koble–Corrigan, Sips, Khan, Hill, Flory–Huggins and Radke–Prausnitz isotherm), have been formulated [20]. This study considers some two parameter isotherms only (Langmuir, Freundlich and Dubinin-Radushkevich). All of the equations and parameters used to model the adsorption isotherms are reported in Table 1 where $C_e$ and $Q_e$ are respectively the concentration of free copper at the equilibrium (mg L$^{-1}$), and the amount of copper adsorbed (mg) per gram of polymer.

The Langmuir equation is valid for monolayer sorption onto a surface with a finite number of identical sites [21]. It assumes a homogeneous surface and no interaction between the adsorbed species on adjacent active sites [22]. From equation presented in Table 1, one can readily deduce that at low sorbate concentrations it effectively reduces a linear isotherm. Alternatively, at high sorbate concentrations, it predicts a constant – monolayer – sorption capacity [23]. A separation factor or equilibrium parameter ($R_l$) was defined from this model [24], as:

$$R_l = \frac{1}{1 + K_l \cdot C_0}$$
where $C_0$ is the highest initial concentration of adsorbate in solution (mg L$^{-1}$).

Depending on its value, the isotherm shape can be interpreted as follows: $R = 0$ for the irreversible case, $0 < R < 1$ for favorable equilibrium, $R = 1$ for the linear case, and $R > 1$ for unfavorable equilibrium [24].

The Freundlich equation is characteristic of multilayer adsorption, with non-uniform distribution of adsorption site and affinities over the heterogeneous surface. The magnitude of exponent $n$ gives an indication on the favorability of adsorption. It is generally stated that the values $n$ in the range of 2–10 represent good, 1–2 moderately difficult and less than 1 poor adsorption characteristics [25]. The Freundlich expression is an exponential equation and therefore, assumes that as the adsorbate concentration increases, the concentration of adsorbate on the adsorbent surface also increases. To determine the maximum adsorption capacity ($Q_m$), it is necessary to operate with constant initial concentration $C_0$ and variable weights of adsorbent; thus $\ln Q_m$ is the extrapolated value of $\ln q$ for $C = C_0$ as previously reported [26].

Dubinin–Radushkevich isotherm is generally applied to express the adsorption mechanism with a Gaussian energy distribution onto a heterogeneous surface. The model has often successfully fitted high solute activities and the intermediate range of concentrations data well. The approach was usually applied to distinguish the physical and chemical adsorption of metal ions [20]. The mean free energy ($E$) can be calculated as follows [27]:

$$E = \left[ \frac{1}{\sqrt{Z \times K_{DR}}} \right]$$

The magnitude of free energy is used for estimating the type of adsorption mechanism. When ranging from 8 to 16 kJ mol$^{-1}$, it indicates an ion-exchange process, beyond 16 kJ mol$^{-1}$ a coordination reaction is expected, and below 8 kJ mol$^{-1}$ physisorption takes place [28]. One of the unique features of the Dubinin-Radushkevich isotherm model lies on the fact that it is temperature-dependent, which when adsorption data at different temperatures are plotted as a
function of logarithm of amount adsorbed versus the square of potential energy, all suitable
data will lie on the same curve, named as the characteristic curve [29, 30].
Thermodynamic data such as adsorption energy can be obtained from Langmuir equation and
can be calculated by using the following equation [31]:
\[ K_l = e^{-\frac{\Delta G_{ads}^o}{RT}} \]

3. Materials and methods

3.1. Materials
Acetoacetic ester (AAE, \( \geq 99\% \)) and the initiator 2,2’-azobisisobutyronitrile (AIBN, \( \geq 98\% \))
were purchased from Aldrich and used without purification. Acrylic acid (AA, 99.5\%)
purchased from Aldrich was purified by distillation under vacuum. Glycine (GLY, grade for
analysis) was obtained from Merck. Ammonia solution (NH\(_4\)OH 30\%, ACS) and sulfuric acid
(H\(_2\)SO\(_4\) 96\%, for analysis) were obtained from Carlo-Erba. Analytical reagent grade, sodium
hydroxide (NaOH), anhydrous sodium sulfate (Na$_2$SO$_4$), copper sulfate (CuSO$_4$·5H$_2$O), nickel sulfate hexahydrate (NiSO$_4$·6H$_2$O) and the reagent grade solvent acetone were purchased from VWR. Cobalt sulfate (extra pure, CoSO$_4$·7H$_2$O) was obtained from Acros Organics.

3.2. Analytical techniques
FTIR spectra were recorded using a Perkin–Elmer Spectrum 100 FTIR spectrometer using the attenuated-total-reflectance (ATR) method. $^1$H-NMR spectra were recorded using a Bruker spectrometer (AMX300) operating at 300 MHz. Deuterium oxide (D$_2$O) was used as the solvent. The chemical shifts are expressed in ppm with respect to tetramethylsilane (TMS). The UV–vis spectra of the polymer solutions were recorded on a Hitachi U4001 spectrophotometer with a scan range of 220–900 nm. Free copper in the solutions was followed on a PHM250 ion analyzer equipped with a copper selective electrode (CSE) (Radiometer-ISE25Cu) and a sulfate reference electrode (Radiometer REF621). Figure 1 and Table 2 present the characteristics of the electrochemical method. The pH was also recorded using a PHM250 ion analyzer equipped with a glass electrode (Radiometer pHG301) and the same sulfate reference electrode.
**Figure 1.** Calibration mean of the copper selective electrode in Na$_2$SO$_4$ 0.1 mol L$^{-1}$ at pH = 5 (based on fourteen replicates).

**Table 2.** Parameters of the electrochemical analytical method in Na$_2$SO$_4$ 0.1 mol L$^{-1}$ at pH = 5 (based on fourteen replicates)

* [32]
3.3. Syntheses

The monomer was obtained by dropwise addition of a glycine 16% aqueous solution (37 mL) to acetoacetic ester (10 mL) under magnetic stirring for 3 hours. The solution was then left overnight to decant (12 hours), and the organic phase containing the key product ethyl-3-glycinatocrotonate (EGC) was collected. The yield of the monomer was 98%, and its purity was tested by FTIR. The linear water-soluble polycarbobetaine named polycarboxyethyl-3-glycinatocrotonate (PCEGC) was synthesized by radical polymerization, as previously reported [13, 33], by mixing EGC, AA and the initiator AIBN (5 minutes). The polymer obtained in bulk was washed with an abundant amount of acetone and oven-dried at 70°C (approximately 35% yield).
Scheme 1. Monomer and polymer syntheses.
3.4. Sorption experiments

The sorption experiments were performed by the batch method (10 mL) in a thermostated cell (25°C) with constant stirring, using PCEGC 0.5 g L\(^{-1}\). The adsorption behavior of the copper ions (Cu(II)) was assayed over a range from 5.10\(^{-5}\) to 5 10\(^{-3}\) mol L\(^{-1}\) and over a pH range from 3 to 6. The ionic strength (I) was fixed at 0.3 mol L\(^{-1}\) with Na\(_2\)SO\(_4\) 0.1 mol L\(^{-1}\). The pH was adjusted with H\(_2\)SO\(_4\) or NaOH. Adsorption isotherms were determined by monitoring free copper decay in the solution and were fitted to the Langmuir, Freundlich and Dubinin-Radushkevich models. The amount of copper adsorbed in (mg/g) at equilibrium (Q\(_e\)), defined as the soluble and precipitated fractions of PCEGC/Cu complex, was calculated from the mass balance of initial and final copper concentrations:

\[
Q_e = \frac{(C_0 - C_e) \times V_{Tot}}{W_{PCEGC}}
\]

where C\(_0\) and C\(_e\) are respectively the initial concentration of copper and the concentration at the equilibrium, V\(_{Tot}\) is the total volume of the solution (L) and W\(_{PCEGC}\) is the weight of the PCEGC (g).

Some of the assays were used to test the selectivity of PCEGC toward copper, cobalt (Co\(^{2+}\)) and nickel (Ni\(^{2+}\)) using electrochemical measurements and UV-visible spectroscopy.

All of the experiments were conducted in triplicate under identical conditions.

The adsorption isotherms were determined by using non-linear regression analysis. The error function employed to evaluate the fit was the second order corrected Akaike information criterion (AICC) defined as follows [25, 28]:

\[
AIC = N \times \ln\left(\frac{RSS}{N}\right) + 2P
\]

\[
AIC_C = AIC + \frac{2P \times (P + 1)}{N - P - 1}
\]

where P is the number of parameters in the model (P=2), N the number of data points and RSS the residual squares sum.
AICc considers the size of the calibration data set and is therefore preferred over the original AIC [34].

3.5. Sorption/desorption cycles experiments
Sorption/desorption experiments were performed over 5 cycles by pH adjustments. A solution of copper 0.005 mol L$^{-1}$ and PCEGC 0.5 g L$^{-1}$ was prepared in Na$_2$SO$_4$ 0.1 mol L$^{-1}$ at pH=5 (the final pH was 4.5). Desorption experiments were performed by decreasing the pH to 2, and the next adsorption cycle was obtained by pH adjustment back to 4.5. The pH was adjusted with H$_2$SO$_4$ or NaOH. This operation was conducted four more times. The free copper in solution was followed by CSE and the concentration was corrected considering the volume increase due to H$_2$SO$_4$ or NaOH addition. The adsorption-desorption behavior of the Cu(II) was assayed in the absence and in the presence of cobalt or nickel ions.

All of the experiments were conducted in triplicate under identical conditions.

3. Results and Discussion

3.1. Characterization
CH$_2$ and CH$_3$ groups of the ethyl function were clearly identified by the presence of a quadruplet at 3.97 ppm and a triplet at 1.03 ppm, respectively, in $^1$H NMR spectra of pure PCEGC. The other hydrogen atoms were observed over the expected range (from 1.43 to 2.54 ppm). No comparison could be performed with the $^1$H NMR spectra of PCEGC/Cu complexes due to their insolvability in D$_2$O.

The main functional groups were identified by FTIR spectroscopy for PCEGC, including the O-H stretching vibration at 3124 cm$^{-1}$; C-H stretching vibration at 2956 cm$^{-1}$; and C=O stretching vibration at 1701 cm$^{-1}$, as previously reported for a similar structure (polycarboxyethyl-3-aminocrotonate) [35, 36]. The results are presented in Figure 1a and
remained unchanged in the PCEGC/Cu complex. No carboxylate asymmetric stretching vibrations were recorded, while a symmetric vibration appeared at 1415 cm\(^{-1}\). This tendency changes in the case of the PCEGC/Cu complex, with the appearance of a medium asymmetric stretching vibration at 1608 cm\(^{-1}\), which is characteristic of copper carboxylates [37]. The difference between these two well-known characteristic bands in the PCEGC/Cu complex (193 cm\(^{-1}\)) indicated that the coordination of the carboxylate groups occurred in a bridged form [38].

The aqueous solution of PCEGC 0.5 g L\(^{-1}\) (I = 0.3 mol L\(^{-1}\) at pH = 5) exhibits an absorbance peak approximately 280 nm, which is specific to carboxylic groups (Figure 1b), while the copper solution absorbs at 816 nm. Figure 1b shows that the maximum absorption for the PCEGC/Cu complex shifted from 816 nm to 702 nm and indicated the coordination interactions between the species. This band is characteristic of square-pyramidal copper(II) complexes [37]. In addition, the specific peak of PCEGC at 280 nm was markedly increased in the presence of copper (from 0.04 to 0.87), confirming the interaction between copper and polycarbobetaine carboxylate groups. This band is assigned to the carboxylate-to-copper charge transfer (ligand-to-metal charge transfer) [38].
Figure 2. IR spectra of PCEGC and PCEGC/Cu complexes (a), and UV-visible spectra of PCEGC (0.5 g L\(^{-1}\)), Cu(II) (0.0005 mol L\(^{-1}\)) and/or Co(II) (0.025 mol L\(^{-1}\)) in 0.1 mol L\(^{-1}\) Na\(_2\)SO\(_4\) at pH = 5 (b).
3.2. Copper complexation

The mechanisms of copper uptake by PCEGC at pH 3.0, 4.0, 5.0, and 6.0 were explored by analyzing the results of the adsorption isotherms (the experimental and predicted isotherms are presented in figure 3). All the parameters extracted from the fitting models are gathered in Table 3 for pH 4 to 6.

![Figure 3. Adsorption isotherms of copper onto PCEGC at various pH values. Experimental data fitted to the Langmuir model (solid line), the Freundlich model (dashed line) and the Dubinin-Radushkevich model (dotted line).](image)

The adsorption capacities at equilibrium (Qe) were low at pH 3.0 (around the detection limits); thus, this pH condition did not explain the binding mechanisms. As shown in Table 3, the difference between the corrected Akaike information criterion of the Freundlich or Dubinin-Radushkevich models and the Langmuir model was greater than nine, providing strong evidence favoring the Langmuir model as the best to describe the interaction between copper and PCEGC [39]. The best fit to the Langmuir model translates the predominantly
homogeneous distribution of the chelating groups on the polymer chains because the Langmuir equation assumes that the adsorbent surface is energetically homogeneous.

Table 3. Isotherm model parameters for Cu(II) adsorption on PCEGC at different pH values.

\(^{a)}\) Corrected Akaike information criterion [39]; \(^{b)}\) Difference between one model AIC\(_C\) and Langmuir AIC\(_C\)

Considering the separation factor (R\(_L\)), adsorption can be considered unfavorable (R\(_L\) > 1), linear (R\(_L\) = 1), favorable (1 > R\(_L\) > 0) or irreversible (R\(_L\) = 0) [40]. R\(_L\) calculated with the Langmuir model indicated the favorable adsorption of Cu(II) onto PCEGC (ranging from 0.2 to 0.02, depending on pH). This observation was confirmed by the values of n (>1) from the Freundlich model [41]. The values of free energy change (Δ_r G < 0) corroborated the spontaneity of the reaction. The maximum adsorption capacity (Qm) was substantially increased (from 15.5 to 264 mg g\(^{-1}\)) as the pH increased (from 3 to 6) and appeared linearly correlated to this parameter (Figure 3).
Figure 4. Maximum adsorption capacity of PCEGC correlated to a) initial pH ($R^2 = 0.98012$); b) final pH ($R^2 = 0.97312$).

The mean free energy of sorption ($E$) derived from the Dubinin-Radushkevich equation provides information on the type of sorption reaction [23]. An energy range from 8 to 16 kJ mol$^{-1}$ indicates an ion-exchange process, and a value above 16 kJ mol$^{-1}$ indicates a coordination reaction [28]. The results presented in Table 1 suggest that coordinative
interactions occurred between PCBets and Cu and confirm the chemisorption of copper onto PCEGC. This conclusion can help to explain previous observations in which Qm increased as the pH increased. The functional groups most likely involved in the complexation reaction are carboxylic groups (COOH). Thus, a higher pH indicates that a larger amount of COOH groups is deprotonated to COO\(^{-}\), thus making them available to complex copper by dative bonds.

Table 4 shows the maximum adsorption capacities of various natural and synthetic materials recently studied for copper recovery from waste or wastewater. PCEGC clearly appears as a promising agent for these applications, especially considering its potential regeneration for future use (as observed for similar PCBets in previous studies) [13].
Table 4. Previously reported adsorption capacities of Cu(II) onto various adsorbents.

<sup>a</sup> 5-aminosalicylic acid (ASA) grafted onto the poly(glycidyl methacrylate) (PGMA)
3.3. Copper selectivity

The influence of nickel (Ni$^{2+}$) and cobalt (Co$^{2+}$) on copper adsorption was investigated by electrochemical measurements (Figure 2). Copper solutions at $5 \times 10^{-4}$ mol L$^{-1}$ (-215.6 < $E_{Cu}$ < -216.3 mV) were prepared in 0.1 mol L$^{-1}$ Na$_2$SO$_4$ at pH = 5 with several different concentrations of metallic ions (Ni$^{2+}$ or Co$^{2+}$). The ratio (R=concentration of metallic ion/concentration of copper) was fixed to 0, 0.5, 1, 2, 5 and 10 (the linearity of the electrode response was lost for higher ratios). Under these conditions, regardless of the metal and the ratio used, the potential of the electrode remained unchanged (with values between -215.6 and -216.3 mV).

![Figure 5](image_url)

*Figure 5.* Selectivity of PCEGC toward Cu(II) (5 $10^{-4}$ mol L$^{-1}$) in the presence of Co$^{2+}$ or Ni$^{2+}$ at varying concentrations in 0.1 mol L$^{-1}$ Na$_2$SO$_4$ at pH = 5 (R=[metallic ion]/[Cu(II)]).

The potential was kept constant (ranging from -235.20 to -236.50 mV) with the addition of PCEGC (0.5 g L$^{-1}$) to the same solutions, suggesting that Co$^{2+}$ and Ni$^{2+}$ were not competing for copper adsorption. The selectivity of PCEGC towards copper was confirmed for R=50 with cobalt by UV-visible analyses (Cf. Figure 1). The spectra of PCEGC/Cu and
PCEGC/Cu/Co were equivalent regarding the wavelength absorption maximum and the absorbance. These assays were not possible with nickel because of the absorbance recovery with copper. In addition to these results, no desorption of copper occurred in favor of nickel ($0 < R < 10$) or cobalt complexation ($0 < R < 50$). This observation agreed with previous results about the selective complexation of copper by glycine groups [50].

### 3.3. Sorption/Desorption cycles

The reusability of PCEGC was explored by pH adjustment at 2 and 4.5 respectively for desorption and adsorption. Figure 6 confirms that the efficiency of copper adsorption was maintained over 5 cycles of PCEGC reuse ($91 \pm 4\%$). The selectivity toward copper in the presence of Ni(II) or Co(II) was also maintained in the same conditions ($94 \pm 3\%$ and $96 \pm 3\%$ respectively).

4. Conclusions

Based on the functionalization of polycarboxyethyl-3-aminocrotonate, novel pH sensitive polycarboxybetaines were successfully prepared with the goal of achieving great complexing properties with copper. The maximal adsorption capacities recorded were shown to be pH-dependent, reaching a value of 264±11 mg of copper per g of polymer at pH=6. The present study also revealed the highly selective properties of PCEGC toward copper in the presence of cobalt, nickel or zinc. This study will be continued to determine the coordinative chemistry of the PCEGC/Cu complexes. The relevance of using PCEGC in environmental applications (such as metal recovery from wastes/wastewaters or environmental sensors) was demonstrated. Using a sustainable strategy based on its pH-sensitive properties, PCEGC reusability and the preservation of the copper adsorption efficiency and selectivity were also confirmed. The use of such materials for environmental applications is greatly encouraged. Further studies will be performed on copper recovery using PCEGC to design a full physicochemical process.

GRAPHICAL ABSTRACT
Highlights:

- A new pH-sensitive polycarbobetaine was synthesized
- Adsorption isotherms were built and modeled
- High adsorption capacities were reached for copper at pH = 5 and pH = 6
- The selectivity toward copper was indicated in the presence of nickel and/or cobalt
- The efficiency of copper adsorption was maintained over 5 cycles of polycarbobetaine reuse
