Abstract	The conversion of CO ₂ and CH ₄ into value-added chemicals is studied in a new geometry of a dielectric barrier discharge (DBD) with multi-electrodes, dedicated to the treatment of high gas flow rates. Gas chromatography is used to define the CO ₂ and CH ₄ conversion as well as the yields of the products of decomposition (CO, O ₂ and H ₂) and of recombination (C ₂ H ₄ , C ₂ H ₆ and CH ₂ O). The influence of three parameters is investigated on the conversion: the CO ₂ and CH ₄ flow rates, the plasma power and the nature of the carrier gas (argon or helium). The energy efficiency of the CO ₂ conversion is estimated and compared with those of similar atmospheric plasma sources. Our DBD reactor shows a good compromise between a good energy efficiency and the treatment of a large CO ₂ flow rate.

1. Introduction

Almost 72% of the total greenhouse effect is attributed to water vapor and clouds, the remainder being mainly the result of CO₂ [1]. Natural greenhouse gas emissions are responsible for bringing the average temperature of the Earth to +15 °C (instead of –18°C) by absorbing its infrared radiation. However, anthropogenic activities reinforce this situation, leading to an increase of greenhouse gas concentrations in the atmosphere [2,3]. In that respect, carbon dioxide (but also methane) figures among the most important greenhouse gases produced by industries and taking part to the global warming. Its production has increased for many decades. Today, it represents 29 gigatons of emission per year and is expected to increase to 36 or 43 gigatons/year, depending upon the energy world policies, i.e. how we will use existing and new energy sources [4]. For this reason, the remediation of CO₂ has received increasing attention in recent years.

Until now, four approaches have been considered to reduce the industrial CO₂ footprint: using renewable energy, using non carbon energy resources, CO₂ capture and CO₂ reforming [5–7]. The latter approach aims at using carbon dioxide as a feedstock and transforming it into value-added products such as carbon monoxide and oxygen, as shown in (1).

This aforementioned reaction is thermodynamically limited and highly endothermic. According to Le Chatelier's principle, a high reaction temperature and a low CO₂ partial pressure are required to achieve a high conversion [7–9]. Owing to the high thermodynamic stability of the CO₂ molecule in standard conditions, its dissociation can only be achieved through endothermic reactions requiring an external energy source. In that respect, conventional chemistry processes have already been used, such as electroreduction of CO₂ [6]. Besides, non-thermal atmospheric plasma processes can be employed such as corona discharges [10,11], dielectric barrier discharges (DBD) [12–

18], gliding-arcs [19,20] and plasma jets [21,22]. Low pressure plasma sources can also be used such as microwave discharges [23,24]. Among these sources, most of the energy required for the dissociation of CO₂ depends on the electron energy distribution function (EEDF). Carbon dioxide can be mixed with methane to form carbon monoxide and molecular hydrogen in (2), but also other products of interest can be formed, such as oxygenated organic molecules and hydrocarbons [25,26].

The conversion of CO₂ and CH₄ by an atmospheric dielectric barrier discharge (DBD) is reported in this study, using Ar as a carrier gas to generate more metastable species and therefore stabilize the discharge. Using a tubular DBD offers a promising and innovative solution since the transformation of CO₂ can be performed “on line”, i.e. directly at the output of industrial chimneys instead of releasing the CO₂ into the atmosphere and hence increase the greenhouse effect. Therefore, it does not require capture, transport or storage of CO₂ and, for instance, could partially close the carbon loop if coupled to green electricity. By using gas chromatography (GC), we demonstrate that this process is efficient to obtain CO and value-added products. Three parameters are evaluated: the CO₂ and CH₄ flow rates, the power supplied to the DBD and the nature of the carrier gas (Ar or He). The energy efficiency of the CO₂ conversion is estimated and compared with those of similar plasma sources.

2. Experimental set-up

2.1. DBD reactor

A cylindrical multi-electrode DBD reactor dedicated to the treatment of elevated gas flow rates has been designed as shown in Fig. 1. It consists of a 2 mm thick tube made in quartz with an external diameter of 34 mm and a length of 100 mm (so as to ensure a long residence time). The gas enters via 16 inlets of 0.75 mm in diameter arranged into a circular pattern, then travels longitudinally through the tubular reactor and finally flows out of the reactor via 16 outlets (same configuration as the inlet). The discharge is generated between six AC high-voltage tubular electrodes set at equal distance from a central tubular electrode which is grounded. The power applied to the high-voltage electrodes is provided by an AFS Generator G10S-V with a maximum power of 1000 W and a variable frequency in the range between 1 and 30 kHz. The distance between the grounded electrode and each high-voltage electrode is the same as the distance between two high-voltage electrodes, namely 3 mm. The grounded electrode is a copper rod with a diameter of 5 mm and a length of 100 mm, while the high-voltage electrodes are copper wires approximately 1 mm in diameter and with the same length of 100 mm. The high-voltage electrodes are encompassed into alumina dielectric tubes with 0.75 mm thickness, as depicted in Fig. 1.

Fig. 1. Schematic diagram of the DBD reactor.

Fig. 2. Schematic diagram of the entire experimental set up.

2.2. Entire set-up

A schematic of the entire experimental setup is shown in Fig. 2. Argon, carbon dioxide and methane are introduced into the reactor via Aalborg volumetric flow meters able to measure flow rates as high as 1800, 120 and 120 mL.min⁻¹, respectively. Argon (or helium) is used as the carrier gas to initiate and maintain the discharge. The total flow rate of the gas mixture supplying the DBD reactor remains fixed at 1920 mL.min⁻¹ while the CO₂ and CH₄ flow rates are both varied from 0 to 120 mL min⁻¹.

The products resulting from the plasma phase reactions are analyzed downstream of the reactor with an online gas chromatograph (Agilent 6890N) equipped with a 60/80 Carboxen 1000 column (Supelco 1-2390-U). The products are analyzed with two detectors: a thermal conductivity detector (TCD) and a flame ionization detector (FID). The conversion of CO₂ and CH₄ are calculated according to Eqs. (3) and (4), respectively, where A represents the peak area assigned to CO₂ or CH₄ in the chromatogram:

$$\text{CO}_2\text{Conversion (\%)} = \chi_{\text{CO}_2} = \frac{A_{\text{CO}_2 \text{ without plasma}} - A_{\text{CO}_2 \text{ with plasma}}}{A_{\text{CO}_2 \text{ without plasma}}} \times 100 \quad (3)$$

$$\text{CH}_4\text{Conversion (\%)} = \chi_{\text{CH}_4} = \frac{A_{\text{CH}_4 \text{ without plasma}} - A_{\text{CH}_4 \text{ with plasma}}}{A_{\text{CH}_4 \text{ without plasma}}} \times 100 \quad (4)$$

The selectivities of H₂, O₂, CO, C₂H₆ and C₂H₄ have been calculated as reported in Table 1, listed as H, O or C based selectivities, depending on the plasma composition (CH₄, CO₂, CO₂/CH₄ respectively).

3. Results

3.1. Effect of the CO₂ and CH₄ flow rates

The plasma is generated in a mixture of CO₂, CH₄ and Ar (or He) to investigate the effect of the reactive gas flow rates on their conversion. The Ar flow rate is set to 1800 mL.min⁻¹ while the CO₂ and CH₄ flow rates can be tuned between 0 and 120 mL.min⁻¹, but the sum of both is always equal to 120 mL.min⁻¹. Fig. 3 represents the CO₂ and CH₄ conversions as a function of the CO₂ and CH₄ flow rates. Both for CO₂ and CH₄, an increase in the flow rate is always correlated with a decrease in its conversion. Indeed, for CO₂ flow rates increasing from 20 to 120 mL.min⁻¹, χ_{CO_2} decreases from 8.3% to 6.1% while χ_{CH_4} decreases from 21.5% to 10.9% when the CH₄ flow rates rise from 20 to 120 mL.min⁻¹. This figure illustrates also that CH₄ is always converted to a larger extent than CO₂, whatever the individual gas flow rates. Chemical reactions in the plasma lead to the dissociation of these molecules, thus generating products that can also recombine to form new species such as H₂, O₂, CO, C₂H₄ and C₂H₆ whose volumetric fractions (f_v) are plotted in Fig. 4(a) as a function of the CO₂ and CH₄ flow rates. Each f_v fraction is calculated as the ratio of the product flow rate to the CO₂/CH₄ mixture flow rate, multiplied by 100. The main products are molecular hydrogen ($f_{v,\text{max}}[\text{H}_2]= 7.73\%$), carbon monoxide ($f_{v,\text{max}}[\text{CO}]= 8.13\%$) and molecular oxygen ($f_{v,\text{max}}[\text{O}_2]= 3.98\%$), the latter being detected only if no CH₄ is injected in the discharge. Other products such as ethylene and ethane are also formed but in smaller proportions ($f_{v,\text{max}}[\text{C}_2\text{H}_4]= 0.52\%$ and $f_{v,\text{max}}[\text{C}_2\text{H}_6]= 1.51\%$). The production of CO is more important with an increase in the CO₂ flow rate, reaching a plateau of approximately 8.10% for CO₂ flow rates higher than 80 mL.min⁻¹. In the same way, the production of hydrogen, ethane and ethylene increases with the CH₄ flow rate. The production of O₂ is only present for pure CO₂ plasma while it disappears after CH₄ addition. That probably means that the CH₄ reactive species interact with oxygen in the discharge. It is quite logical that the decomposition of CO₂ favors the production of CO and O₂ while the decomposition of CH₄ leads to the production of H₂, C₂H₄ and C₂H₆ but also of carbon black powder (not detected by gas chromatography).

Fig. 3. CO₂ and CH₄ conversions as a function of the CO₂ and CH₄ flow rates with $\Phi_{\text{Tot}} = 1920$ mL.min⁻¹, $\Phi_{\text{Ar}} = 1800$ mL.min⁻¹, $\Phi_{\text{CO}_2} = \Phi_{\text{CH}_4} = 120$ mL.min⁻¹, plasma power = 45 W, frequency = 19.5 kHz.

Fig. 4. (a) Volumetric fractions of H₂, CO, O₂, C₂H₄ and C₂H₆ (using the TCD) and (b) C-based selectivity of the quantified gaseous products as a function of the CO₂ and CH₄ flow rates with $\Phi_{\text{Tot}} = 1920$ mL.min⁻¹, $\Phi_{\text{Ar}} = 1800$ mL.min⁻¹, $\Phi_{\text{CO}_2} = \Phi_{\text{CH}_4} = 120$ mL.min⁻¹, plasma power = 45 W, frequency = 19.5 kHz.

The selectivities of these products have also been calculated using the formulas from Table 1 and considering three cases:

- (1) When using CH₄ as unique reactive gas, the H-based selectivities are approximately 26% for H₂, 32% for C₂H₆ and 6% for C₂H₄. As $S_H(H_2) + S_H(C_2H_6) + S_H(C_2H_4) + S_H(\text{other}) = 100\%$, other products may be considered, i.e. CH_x non-gaseous products which are assumed to deposit on the inner walls of the reactor, especially on the surface of the high voltage central electrode.
- (2) When using CO₂ as unique reactive gas, the O-based selectivities lead to $S_O(O_2) + S_O(CO) = 48.2 + 49.2 = 97.4$. This value is very close to 100% and if experimental errors are considered – in particular the uncertainties of the flowmeters (<3%) – then we can conclude that CO₂ is virtually only converted to molecular oxygen and carbon monoxide.
- (3) When using a CH₄/CO₂ mixture, the C-based selectivities of three gaseous carbonated products (namely CO, C₂H₆ and C₂H₄) are plotted as a function of CO₂ flow rate in Fig. 4(b). According to the relation $S_C(CO) + S_C(C_2H_6) + S_C(C_2H_4) + S_C(\text{other}) = 100\%$, an increase in $S_C(\text{other})$ is evidenced with a rise in the CH₄ flow rate. We believe that this can be due to solid carbon deposit, formation of acetylene and liquid/gaseous formaldehyde.

	H-based selectivities (CH ₄ plasma)	O-based selectivities (CO ₂ plasma)	C-based selectivities (CH ₄ /CO ₂ plasma)
S_{H_2} (%)	$\frac{n_{H_2}^{\text{produced}}}{2 \cdot n_{CH_4}^{\text{converted}}} \times 100$	–	–
S_{O_2} (%)	–	$\frac{n_{O_2}^{\text{produced}}}{n_{CO_2}^{\text{converted}}} \times 100$	–
S_{CO} (%)	–	$\frac{n_{CO}^{\text{produced}}}{2 \cdot n_{CO_2}^{\text{converted}}} \times 100$	$\frac{n_{CO}^{\text{produced}}}{n_{CO_2}^{\text{converted}} + n_{CH_4}^{\text{converted}}} \times 100$
$S_{C_2H_4}$ (%)	$\frac{n_{C_2H_4}^{\text{produced}}}{n_{CH_4}^{\text{converted}}} \times 100$	–	$\frac{2 \cdot n_{C_2H_4}^{\text{produced}}}{n_{CO_2}^{\text{converted}} + n_{CH_4}^{\text{converted}}} \times 100$
$S_{C_2H_6}$ (%)	$\frac{3 \cdot n_{C_2H_6}^{\text{produced}}}{2 \cdot n_{CH_4}^{\text{converted}}} \times 100$	–	$\frac{2 \cdot n_{C_2H_6}^{\text{produced}}}{n_{CO_2}^{\text{converted}} + n_{CH_4}^{\text{converted}}} \times 100$

Table 1 Formulas for the H, O or C based selectivities of H₂, O₂, CO, C₂H₆ and C₂H₄ (n is the number of moles).

The case of solid carbon deposit on the central copper electrode area clearly appears after a few minutes of plasma treatment. The apparent granular texture of this deposit may be responsible for local electrical peak effects, thus leading to a more filamentary discharge. As a result, the CO₂ conversion would change in case of prolonged use of the reactor. No arc has been formed, which otherwise would have prematurely deteriorated the barrier, and hence the durability of the reactor. To prevent these problems, coke deposit can easily be removed by cleaning the inner walls of the reactor and polishing them with sandpaper. Another convenient way is to apply a pure CO₂ or pure O₂ plasma to remove the coke deposit.

3.2. Effect of the power

Fig. 5 shows the CH₄ and CO₂ conversions versus the power applied to the DBD in the range between 30 W and 80 W for $\Phi_{Ar} = 1680 \text{ mL min}^{-1}$, $\Phi_{CO_2} = \Phi_{CH_4} = 120 \text{ mL min}^{-1}$ and an AC frequency of 19.5 kHz. The CO₂ conversion increases from 2.0% to 7.5% upon rising power, while the CH₄ conversion increases from 6.7% to 14.8% in the same power range. The two conversions can be considered as linearly

increasing with the power since their correlation coefficients are $r^2(\text{CO}_2) = 0.976$ and $r^2(\text{CH}_4) = 0.899$. The slopes of both curves are almost the same, consistently with the results of Zheng et al. performed in a two-electrode DBD reactor [27]. It is also clear that the methane conversion is always higher than χ_{CO_2} (difference of at least 5%) thanks to its lower bond energy. The volumetric fractions of H_2 , CO , C_2H_4 , C_2H_6 plotted in Fig. 6 versus the power indicate that the production of syngas (hydrogen and carbon monoxide) also increases linearly with the power, and both products are formed nearly equally, yielding a syngas ratio close to 1. A linear increase is also observed in the case of C_2H_4 and C_2H_6 , although the slopes are less significant.

Fig. 5. Conversions of CO_2 and CH_4 versus the power ($\Phi_{\text{Ar}} = 1680 \text{ mL.min}^{-1}$; $\Phi_{\text{CO}_2} = \Phi_{\text{CH}_4} = 120 \text{ mL.min}^{-1}$; frequency = 19.5 kHz).

Fig. 6. Volumetric fractions of H_2 , CO , C_2H_4 and C_2H_6 (using the TCD) versus the power ($\Phi_{\text{Ar}} = 1680 \text{ mL.min}^{-1}$; $\Phi_{\text{CO}_2} = \Phi_{\text{CH}_4} = 120 \text{ mL.min}^{-1}$; frequency = 19.5 kHz).

3.3. Effect of the carrier gas

The influence of the carrier gas (argon or helium) is investigated for the same flow rate set to 1800 mL.min^{-1} and the reactive gas flow rates set to $\Phi_{\text{CO}_2} = \Phi_{\text{CH}_4} = 60 \text{ mL.min}^{-1}$. The nature of the carrier gas seems to have an important impact on the conversion of CO_2 and CH_4 ; see Fig. 7a. The conversion of CH_4 is indeed higher in the presence of helium than with argon (respectively 21.4% and 16.4%) while the opposite effect is observed for the conversion of CO_2 since $\chi_{\text{CO}_2} = 6.8\%$ with helium and $\chi_{\text{CH}_4} = 11.5\%$ with argon. It is also worth mentioning that for the same plasma power (60 W) and frequency (17.1 kHz), a filamentary discharge and a glow discharge are obtained with argon and helium, respectively, as shown in Fig. 7b and c.

Fig. 7. (a) Conversions of CH_4 and CO_2 in $\text{Ar}/\text{CO}_2/\text{CH}_4$ and $\text{He}/\text{CO}_2/\text{CH}_4$ plasmas with $\Phi_{\text{Tot}} = 1920 \text{ mL.min}^{-1}$, Φ_{Ar} or $\Phi_{\text{He}} = 1800 \text{ mL.min}^{-1}$, $\Phi_{\text{CO}_2} = \Phi_{\text{CH}_4} = 60 \text{ mL.min}^{-1}$, plasma power = 60 W and frequency = 17.1 kHz; (b) picture of the $\text{Ar}/\text{CO}_2/\text{CH}_4$ discharge, illustrating the filamentary behavior; (c) picture of the $\text{He}/\text{CO}_2/\text{CH}_4$ discharge, illustrating the glow mode.

4. Discussion

4.1. Effect of the CO₂ and CH₄ flow rates on the plasma reactivity and reaction products formed in the CO₂/CH₄ conversion process

4.1.1. Overview of the important reactions

Plasmas are complex media where several hundred reactions of production and consumption can occur [28,29]. The most plausible mechanisms for the formation and consumption of intermediate and value-added products in the CO₂/CH₄ gas mixture are listed in Table 2. In the following sections, we explain how the most important reaction products are formed.

Table 2 Reaction pathways for the formation and consumption of intermediate and value-added products of CH₄ and CO₂ conversion.

	Reaction	Rate constant	Ref.
(R1)	CH ₄ + e → CH ₃ [•] + H [•] + e	σ ₃ [•]	[30]
(R2)	CH ₂ + O [•] → CO + H ₂	5.53 × 10 ⁻¹¹ cm ³ s ⁻¹	[31]
(R3)	CH ₃ [•] → CH ₂ [•] + H [•]	1.69 × 10 ⁻⁰⁸ cm ³ s ⁻¹	[32]
(R4)	CH ₃ [•] + e → CH ₂ [•] + H [•]	2.25 × 10 ⁻⁰⁸ cm ³ s ⁻¹	[30,33]
(R5)	CH ₃ [•] + e → CH [•] + H ₂	7.88 × 10 ⁻⁰⁹ cm ³ s ⁻¹	[30,33]
(R6)	CH ₃ [•] + H [•] → CH ₂ [•] + H ₂	1.00 × 10 ⁻¹⁰ cm ³ s ⁻¹	[32]
(R7)	CH ₄ + H [•] → CH ₃ [•] + H ₂	5.83 × 10 ⁻¹³ cm ³ s ⁻¹	[32]
(R8)	CH ₄ ⁺ + H [•] → CH ₃ ⁺ + H ₂	1.00 × 10 ⁻¹¹ cm ³ s ⁻¹	[34]
(R9)	H [•] + H [•] → H ₂	1.44 × 10 ⁻¹⁴ cm ³ s ⁻¹	[35]
(R10)	CO ₂ + H [•] → CO + OH [•]	1.40 × 10 ⁻²⁹ cm ³ s ⁻¹	[36]
(R11)	CH [•] + O [•] → CO + H [•]	6.90 × 10 ⁻¹¹ cm ³ s ⁻¹	[32]
(R12)	CO ₂ + CH [•] → 2CO + H [•]	9.68 × 10 ⁻¹³ cm ³ s ⁻¹	[31]
(R13)	CH ₃ [•] + CH ₃ [•] → C ₂ H ₆	4.20 × 10 ⁻¹¹ cm ³ s ⁻¹	[37]
(R14)	C ₂ H ₅ [•] + H [•] → C ₂ H ₆	2.25 × 10 ⁻¹⁰ cm ³ s ⁻¹	[38]
(R15)	C ₂ H ₅ [•] + CH ₄ → C ₂ H ₆ + CH ₃ [•]	1.83 × 10 ⁻²⁴ cm ³ s ⁻¹	[36]
(R16)	C ₂ H ₆ + e → C ₂ H ₅ [•] + H [•] + e	σ ₁₈ [•]	[39]
(R17)	C ₂ H ₅ [•] + e → C ₂ H ₄ + H [•] + e	σ ₁₉ [•]	[39]
(R18)	CH ₄ + CH [•] → C ₂ H ₄ + H [•]	9.74 × 10 ⁻¹¹ cm ³ s ⁻¹	[32]
(R19)	CH ₃ [•] + CH ₂ [•] → C ₂ H ₄ + H [•]	7.01 × 10 ⁻¹¹ cm ³ s ⁻¹	[32]
(R20)	C ₂ H ₅ [•] + O [•] → C ₂ H ₄ + OH [•]	4.40 × 10 ⁻¹¹ cm ³ s ⁻¹	[31]
(R21)	CO ₂ + e → CO + O [•] + e	σ ₂₃ [•]	[40]
(R22)	CO ₂ + e ⁻ → CH ₄ CO + O [•] + e ⁻	σ ₂₄ [•]	[40]
(R23)	CO ₂ + O [•] → CO + O ₂	2.01 × 10 ⁻¹⁰ cm ³ s ⁻¹	[41]
(R24)	CO ₂ ⁺ + e → CO + O [•]	2.71 × 10 ⁻⁰⁷ cm ³ s ⁻¹	[33]
(R25)	CH ₃ [•] + O [•] → H ₂ CO + H [•]	1.12 × 10 ⁻¹⁰ cm ³ s ⁻¹	[42]
(R26)	CH ₂ [•] + O ₂ → H ₂ CO + O [•]	5.39 × 10 ⁻¹³ cm ³ s ⁻¹	[32,43]

4.1.2. Production of hydrogen

Several chemical reactions give rise to the production of molecular hydrogen through the dissociation of hydrocarbon species upon collision with an atom (R2), an electron (R5) or an H radical (R6, R7 and R8). The rate constants of these reactions are in the order of 10⁻¹³–10⁻¹⁰ cm³.s⁻¹, except for R5 which is somewhat higher (7.88*10⁻⁹ cm³.s⁻¹) as the collision occurs between an energetic electron and an ion. Although the rate constant of R9 is a bit lower than the other ones (1.44*10⁻¹⁴ cm³.s⁻¹), the recombination of two H radicals may be considered as very important since v = k₁₁[H]² and H is produced in many other reactions such as R3, R4, R11, R12, R16, R17, R18, R19 and R25. Electron impact reactions R16 and R17 are not described with a rate constant but with a cross section s which depends on the electron temperature.

4.1.3. Production of CO

The formation of CO is directly correlated with the dissociation of CO₂. The reactions responsible for the production of CO are given by R2, R10, R11, R12, R21, R22, and R23 [44]. (R21) is electron impact dissociation of CO₂ into CO and O, which is the most important process in CO₂ splitting. When CH₄ is present, the O atoms will be further consumed by R2, R11, R20, R23 and R25 and this explains the higher CO₂ conversion when more CH₄ is present in the gas mixture. Indeed, as stated by the Le Chatelier's principle, the dissociation is more favorable as one (or both) of the reaction products is constantly consumed. This effect has been demonstrated in the literature: Tagawa et al. have observed an increasing CO₂ conversion by placing an O₂ trapper membrane into a CO₂/CH₄ discharge in order to separate O₂ from the gas stream. As a consequence, the CO/CO₂ equilibrium is more shifted to CO [45].

4.1.4. Production of ethane

The recombination of two CH_3^* radicals can lead to the production of ethane according to reaction (R13). R14 and R15 could also lead to the production of ethane but are less probable. Indeed, as computed by Snoeckx et al. in the case of a similar atmospheric DBD source supplied in $\text{CH}_4\text{-CO}_2$, the density of CH_3 is always higher than the one of C_2H_5 [29].

4.1.5. Production of ethylene

The formation of ethylene may result from a two-step collisional mechanism, where first an electron collision leads to the dissociation of C_2H_6 into C_2H_5^* and H radicals (R16), followed by a second electron collision with C_2H_5^* resulting in the abstraction of a H radical to produce ethylene (R17). This simple mechanism can explain why $f_V[\text{C}_2\text{H}_4]$ is always lower than $f_V[\text{C}_2\text{H}_6]$.

4.1.6. Other reaction products

Formaldehyde traces have also been detected. Their formation can result from CH_3 radicals (R25) or to a lower extent from CH_2 radicals (R26). Other oxygenated products have not been detected at the conditions under study, probably because their amounts are under the limit of detection of the gas chromatography detectors. According to the literature, the formation of other oxygenated organic molecules such as acetic acid or methanol may also occur in a plasma [17,46,47].

The higher volumetric fraction of H_2 , compared to ethane and ethylene, can be explained according to several chemical reactions (R2, R5, R6, R7, R8 and R9). Indeed, there are more reactions for H_2 and H^* formation compared to reactions for C_2H_6 and C_2H_4 formation. Moreover, there are more reactions consuming C_2H_6 or C_2H_4 than consuming H_2 . C_2H_6 or C_2H_4 is indeed very easily consumed once it is produced. That is why the H_2 amount is always higher than the amounts of C_2H_6 and C_2H_4 .

4.2. Effect of the power

The linear increase of CO_2 and CH_4 conversions as a function of the power results from a linear increase in the electron density (Fig. 5). Indeed, the dissociation of C–H and C=O bonds requires energies of a few eV that may be mostly transferred from the electrons. An increase in the plasma power can induce higher electron temperatures and higher electron densities. In our case, the increase in electron temperature may be assumed as negligible since in a classical DBD, it would induce a stronger filamentary regime that has not been observed here. Increasing the plasma power can also induce higher electron densities that can be assumed as linearly depending on the power if the electron permeability and the electric field profile are considered as weakly dependent on the applied power.

For the production of C_2H_4 and C_2H_6 , a linear increase upon increasing power is also observed, but the slopes are less pronounced than for CO and H_2 . This is probably due to the fact that the production of these molecules is not simply based on one electron impact reaction, like the formation of H_2 from CH_4 and the splitting of CO_2 into CO . Indeed, in order to obtain C_2H_6 , two CH_3^* radicals are necessary (R13) while to obtain C_2H_4 , two electronic collisions with C_2H_6 are required (R16 and R17).

4.3. Effect of the carrier gas

According to Fig. 7, χ_{CH_4} is always higher than χ_{CO_2} whatever the nature of the carrier gas. Indeed, in a plasma, the dissociation of CH_4 is easier than for CO_2 since the bond dissociation energy of C–H (4.48 eV) is lower than the bond dissociation energy of C=O (5.52 eV) [48].

However, the fact that CH_4 is more efficiently dissociated in He than in Ar, whereas CO_2 is more efficiently dissociated in Ar than in He, is less straightforward. The reason is that the shape of the electron energy distribution function (EEDF) is different when the plasma is in the filamentary regime (Ar) or in the glow regime (He). The EEDF of these two regimes is sketched in Fig. 8, assuming Maxwellian distributions (thermodynamic equilibrium) for the sake of clarity [49]. The bond dissociation energies of C–H and C=O are also reported in Fig. 8. In the filamentary regime, the EEDF is characterized by (i) a number of warm electrons much lower than in a glow discharge but also by (ii) a tail extending toward higher energies, meaning that the hot electrons (even if not in a large number) can be involved into new collisional processes, which require a stronger activation energy [50]. In the case of the CH_4 dissociation, all the electrons that contribute to breaking of the C–H bonds, must be located at the right side of $\text{BDE}(\text{C–H})$ and under the EEDF curves: this corresponds to the area A_1 in the glow regime (He) and A_3 in the filamentary regime (Ar) (see insert in Fig. 8). As A_1 is larger than A_3 , more electrons can participate to the dissociation of CH_4 in the case of He, hence this explains why $(\chi_{\text{CH}_4})_{\text{He}} > (\chi_{\text{CH}_4})_{\text{Ar}}$.

On the other hand, a higher electron energy is needed for breaking the C=O bonds of CO_2 : all electrons that contribute to this bond breaking, must be located at the right side of $\text{BDE}(\text{C=O})$, and under the EEDF curves: this corresponds to area A_2 in the glow regime (He) and to area A_4 in the filamentary regime (Ar). As A_4 is larger than A_2 , more electrons can participate to the dissociation of CO_2 in Ar than in He, and this explains why $(\chi_{\text{CO}_2})_{\text{Ar}} > (\chi_{\text{CO}_2})_{\text{He}}$. Finally, if we consider the areas which correspond to the electrons that can contribute to the dissociation of C–H and C=O bonds for both the glow and filamentary regimes, it appears that $A_1 > A_3 > A_4 > A_2$. Hence, this corresponds to $(\chi_{\text{CH}_4})_{\text{He}} > (\chi_{\text{CH}_4})_{\text{Ar}} > (\chi_{\text{CO}_2})_{\text{Ar}} > (\chi_{\text{CO}_2})_{\text{He}}$, which is indeed observed in Fig. 7. Therefore, the CO_2 conversion is the lowest in helium since A_2 is the smallest among the four areas. In other terms, the number of electrons available in a He discharge for the conversion of CO_2 is very small as the energy of these electrons has to be equal to or higher than the activation energy to break C=O (i.e. 5.52 eV). In summary, the nature of the carrier gas – and consequently the regime (glow or filamentary) of the DBD – directly impacts the shape of the EEDF and therefore the electron collision processes that may occur.

Fig. 8. Schematic sketch of the EEDFs in the case of a glow discharge (He) and a filamentary discharge (Ar) at thermodynamic equilibrium. Also indicated are the bond dissociation energies (BDE) for C–H and C=O bonds. The insert shows the fractions of electrons that can contribute to dissociation of C–H and C=O bonds in both regimes (see text for more explanation).

4.4. Conversion, specific energy input and energy efficiency: comparison with literature

The specific energy input (SEI) corresponds to the energy density (E_d) in $\text{J}\cdot\text{cm}^{-3}$, and can also be expressed in eV molecule^{-1} as defined by the following equations:

$$E_d (\text{J cm}^{-3}) = \frac{\text{Power (J s}^{-1})}{\text{Gas flow rate (cm}^3 \text{ s}^{-1})} \quad (5)$$

$$\text{SEI (eV molecule}^{-1}) = \frac{E_d (\text{J cm}^{-3}) \times 6.24 \times 10^{18} (\text{eV J}^{-1}) \times 24500 (\text{cm}^3 \text{ mol}^{-1})}{6.022 \times 10^{23} (\text{molecule mol}^{-1})} \quad (6)$$

The energy efficiency of the CO_2 conversion (η_{CO_2}) has been calculated (in %) from the conversion χ_{CO_2} , the enthalpy of (2) namely $\Delta H_{298\text{K}}^0 = 247.3 \text{ kJ}\cdot\text{mol}^{-1} = 2.56 \text{ eV molecule}^{-1}$ and the SEI value, according to the following equation:

$$\eta_{\text{CO}_2} (\%) = \frac{\chi_{\text{CO}_2} (\%) \times \Delta H_{298\text{K}}^0 (\text{eV molecule}^{-1})}{\text{SEI (eV molecule}^{-1})} \quad (7)$$

The same equation can be written for the energy efficiency of the CH_4 conversion (η_{CH_4}). Hence, the energy efficiency is separately defined for CO_2 and CH_4 in this article. Eq. (7) indicates that an increase in the SEI systematically induces a decrease in η , at least when the conversion stays constant, and this means that we should have a SEI value as low as possible to obtain a more energy efficient process. This is indeed clear from Fig. 9, where the energy efficiencies of both CH_4 and CO_2 clearly drop upon higher SEI. For a SEI as low as $5.7 \text{ eV molecule}^{-1}$, $\eta_{\text{max}}(\text{CO}_2) = 3.3\%$ while $\eta_{\text{max}}(\text{CH}_4) = 4.9\%$.

Fig. 9. Energy efficiency as a function of specific energy input in our experimental set-up with $\Phi_{\text{Tot}} = 1920 \text{ mL}\cdot\text{min}^{-1}$, $\Phi_{\text{Ar}} = 1800 \text{ mL}\cdot\text{min}^{-1}$, $\Phi_{\text{CO}_2} = \Phi_{\text{CH}_4} = 120 \text{ mL}\cdot\text{min}^{-1}$, plasma power = 45 W, frequency = 19.5 kHz.

A comparison of our multiple electrode DBD reactor with other atmospheric plasma sources is presented in Table 3. This table reports various plasma sources: DBD, AC glow discharges, pulsed corona and gliding arcs with different geometries and specific operating parameters, namely: frequency, power given by authors, nature of the carrier gas or reactive gas, and CO_2 flow rate. Note that some of these experiments apply to pure CO_2 splitting, while others refer to dry reforming (i.e., conversion of both CO_2 and CH_4). However, we focus here only on the CO_2 conversion. Also, it should be noted that some experiments were carried out for the pure greenhouse gases, while others made use of a carrier gas. The conversion and energy efficiency are in general higher in a carrier gas but it is obviously less interesting for applications. The optimal CO_2 conversions for all these cases are plotted in Fig. 10 as a function of the corresponding SEI while their energy efficiencies are plotted in Fig. 11 as a function of the CO_2 flow rates. In these figures, each squared number refers to one of the plasma sources listed in Table 3.

Fig. 10. CO₂ conversions vs SEI for the various plasma sources listed in Table 3.

Fig. 11. Energy efficiency (%) of the various atmospheric plasma sources listed in Table 3, as a function of the CO₂ flow rates. The area in the left bottom is enlarged as an insert, placed in the right top of the figure.

A first remark is that no atmospheric plasma source can reach a χ_{CO_2} higher than 25%. Moreover, no general trend can be deduced: the cloud of points indicates that some plasma sources are very energy-consuming with high χ_{CO_2} (#8, #14 and #15) while some others are much more dedicated to CO₂ reforming at a lower energy cost (#1, #4, #7, #17, #18 and #19) since they are located close to the vertical line at 2.56 eV molecule⁻¹, standing for the enthalpy of reaction (2). The plasma source #7 shows a good energy efficiency, but is not suitable as it can handle CO₂ flow rates of only 0.8 mL min⁻¹. The plasma sources #17 and #19 present interesting conversions for SEI as low as ours, but with the disadvantage of their geometry, which is a pulsed corona and a gliding arc, respectively. Indeed, the advantage of using a tubular DBD lies in the ability to place it at the nozzle exit of a combustion process to treat the entire gas flow since all the gas passes through the discharge zone. On the contrary, a pulsed corona and a gliding arc can exhibit “dead volumes” where the gas passes through the reactor without being treated in the plasma zone. Furthermore, the corona source is not adapted for high flow rates treatment as its discharge volume is not that important, which makes it a good candidate only to handle low flow rates. The plasma source #4 is an interesting alternative to our plasma process. In our case, the CO₂ conversion is not so high but the SEI is quite low, so this yields a good energy efficiency, as shown in Fig. 11 (#1). Our plasma source shows a good compromise between a high energy efficiency and the treatment of a significant CO₂ flow rate, probably thanks to the multielectrode configuration.

#	Plasma source		Frequency (kHz)	Power (W)	Carrier or reactive gas	CO ₂ flow rate (mL min ⁻¹)	Ref.
	Type	Geometry					
1	DBD	Tube multi-electrodes	19.5	45	Ar	120	Our reactor
2	DBD	Tube	30	100	/	50	[16]
3	DBD	Plane	30	500	CH ₄	500	[47]
4	DBD	Tube	2.2	45	Ar	80	[27]
5	DBD	Plane	25	15	He/CH ₄	5	[26]
6	DBD	Tube	25	100	CH ₄	60	[51]

18	DBD	Tube	30	60	Ar/CH ₄	60	[55]
19	Gliding arc	"V" shaped electrode	20	225	/	2000	[20]

Table 3 Comparison of various plasma sources dedicated to the conversion of CO₂ at atmospheric pressure. The CO₂ conversions vs SEI and the energy efficiency as a function of CO₂ flow rate for all these cases are reported in Figs. 10 and 11, respectively.

5. Conclusion

The production of syngas (CO and H₂), C₂H₄ and C₂H₆ has been achieved at atmospheric pressure in a dielectric barrier discharge operating in CO₂ and CH₄, with Ar or He as carrier gases. The main mechanisms responsible for the production of these compounds have been discussed. In this study, the effect of the concentration of CO₂/CH₄ in the mixture on the conversion has been demonstrated. Furthermore, the effect of power has also been reported, showing a linear increase in the CO₂ and CH₄ conversions but also in the production of syngas as a function of the supplied power. Finally, the energy efficiency of the CO₂ conversion has been calculated and compared with those of other atmospheric plasma sources. Our DBD reactor offers very encouraging results as it offers one of the best compromises between a high energy efficiency and the treatment of a large CO₂ flow rate.
