Abstract

Atmospheric ozone concentration measurements mostly depend on spectroscopic methods that cover different spectral regions. Despite long years of measurement efforts, the uncertainty goal of 1% in absolute line intensities has not been reached yet. Multispectral inter-comparisons using both laboratory and atmospheric studies reveal that important discrepancies exist when ozone columns are retrieved in different spectral regions. Here, we use ground based FTIR to study the sensitivity of ozone columns on different spectroscopic parameters as a function of individual bands for identifying necessary improvements of the spectroscopic databases. In particular, we examine the degree of consistency that can be reached in ozone retrievals using spectral windows in the 5 and 10 μm bands of ozone. Based on the atmospheric spectra, a detailed database inter-comparison between HITRAN (version 2012), GEISA (version 2011) and S&MPO (as retrieved from the website at the end of 2015) is made. Data from the 10 μm window are consistent to better than 1%, but there are larger differences when the windows at 5 μm are included. The 5 μm results agree with the results from 10 μm within $\pm 2\%$ for all databases. Recent S&MPO data are even more consistent with the desired level of 1%, but spectroscopic data from HITRAN give about 4% higher ozone columns than those from GEISA. If four sub-windows in the 5 μm band are checked for

consistency, retrievals using GEISA or S&MPO parameters show less dispersion than those using HITRAN, where one window in the P -branch of the $\nu_1 + \nu_3$ band gives about 2 % lower results than the other three. The atmospheric observations are corroborated by a direct comparison of the spectroscopic databases, using a simple statistical analysis based on intensity weighted spectroscopic parameters. The bias introduced by the weighted average approach is investigated and it is negligible if relative differences between databases do not correlate with line intensities. This is the case for the comparison of HITRAN with GEISA in the 10 μm region and the agreement between the simple analysis and the full retrieval is better than 0.1%. At 5 μm biases might be as high as 1.4 %, and the proposed method is thus limited to the same level of accuracy. Implications of the new data for database improvements and further studies, in particular in the 5 μm region, are discussed.

Keywords: ozone, atmospheric composition, remote sensing, FTIR, MIR, spectroscopic database

1. Introduction

The triatomic allotrope of oxygen, ozone (O_3), is a key molecule in Earth's atmosphere. As precursor molecule for atmospheric radicals (NO_3 , OH) it plays a central role in atmospheric oxidation. Ozone also filters harmful solar ultraviolet (UV) radiation and thus is crucial to the evolution of life as we know it. The molecule has direct impact on air quality, agricultural productivity, and the ecosystem with corresponding economic consequences. Accurate and traceable concentration measurements of this molecule thus are a priority for health and air quality authorities as well as for atmospheric and climate scientists, which has made ozone one of the key themes of dedicated global atmospheric observation programs, such as IGACO-O3/UV.¹

¹Integrated Global Atmospheric Chemistry Observations for ozone and UV as part of the Global Atmospheric Watch (GAW) Programme of the World Meteorological Organisation for providing reliable scientific data and information on the chemical composition of the atmosphere, its natural and anthropogenic change, and helping to improve the understanding of interactions between the atmosphere, the oceans and the biosphere.

Due to its high reactivity and the impossibility to prepare a stable reference standard along with the fact that ozone has rich and strong absorption features covering all spectral regions from the far IR to the UV, O₃ concentration measurements are commonly based on spectroscopic methods. These measurements thus depend on the molecular spectroscopic constants describing the interaction with light, which have to be determined experimentally. Indeed, the recommended primary method for in-situ ozone measurements in ambient air hinges on the absorption cross section in the Hartley band at 253.65 nm, whose actually recommended value suffers from a relative uncertainty of 2.1 % (at the 95 % level of confidence) [1]. In view of the need for reliable long term measurements of ozone changes of a few percent per decade [2–5], traceable spectroscopic data with a much lower level of uncertainty are desired and redeterminations of this cross section value are thus under way [6–8]. A target uncertainty for concentration measurements and remote sensing of atmospheric ozone is one percent [1, 7, 9, 10], or below. This would also allow meaningful retrieval of tropospheric ozone from satellite data where the total column is dominated by the stratospheric contribution (~ 90 %). Achieving and well characterizing this level of uncertainty will also make an important contribution to the United Nations effort in documenting long-term ozone trends [11].

In order to harmonize the spectroscopic data on ozone, the most recent mid-IR intensity studies in the 10 μ m range [2–5, 12–15] have been critically reviewed [16] and the databases have been updated concordantly after 2004 [17–19]. Because three of four recent measurements showed a dispersion of just $\pm 0.8\%$, it was recommended to reduce the database values by roughly 4 % which corresponded to the average of the three consistent data sets. The recommendation thus has effectively ignored the recent measurement of Smith et al. [12] even though it was consistent with previous measurements and the actual recommendation (HITRAN 2000) at that time and this was done without pointing out why this particular measurement should be less reliable than the other studies.

Interestingly, recent direct UV (300–315 nm) - IR (10 μ m) inter-comparison measurements in the laboratory [20, 21], in the atmosphere from ground [22] or using satellite instruments [23] have questioned the thus obtained consistency of the updated spectroscopic parameters: using either of the two spectral regions, inter-comparisons

often find a difference of about 4 % in the derived ozone concentrations or columns. This could possibly indicate that the original HITRAN 2000 database [24] values are more consistent with recommended UV data. A similar difference of $(3.6 \pm 1.0) \%$ has
45 been found in another UV - IR inter-comparison based on simultaneous measurements at the Hg emission line at 253.65 nm and around 1133.5 cm^{-1} in the ν_1 band [25]. Moreover, using the same two databases (HITRAN 2004 or 2008), the ACE-FTS mission team has decided to neglect the results from ozone spectroscopic data in the $5 \mu\text{m}$ band (in the $\nu_1 + \nu_2$ band around 1800 cm^{-1} and in the $\nu_1 + \nu_3$ band around 2100 cm^{-1}), because
50 of apparent discrepancies with the results obtained from retrieval in the $10 \mu\text{m}$ fundamental region [23]. This has triggered another inter-comparison study [26] between the integrated absorption in the Chappuis band (515 - 715 nm) and the $\nu_1 + \nu_3$ combination band. There, however, no inconsistencies in recommended databases have been found, but optical densities in the visible were very weak though ($< 4 \%$). Thomas et al. [27]
55 studied recently possible inconsistencies between the 5 and $10 \mu\text{m}$ regions by absolute measurements in each of these two regions. Their results at $10 \mu\text{m}$ are compatible with the 2004 or 2008 HITRAN databases and about 2 % lower than the actual databases in the $5 \mu\text{m}$ region, which, if significant, could even increase the observed discrepancy in the satellite data [23, 28].

60 Very recently, the first direct inter-comparison between the 3 and $10 \mu\text{m}$ as well as the 4 and $10 \mu\text{m}$ regions has been published [29]. This study is based on ground based FTIR solar absorption spectra and systematic differences of up to 7 % between the different regions have been revealed, most likely due to inconsistencies in the spectroscopic data.

65 Given these many seemingly conflicting results, further inter-comparisons, ideally using identical conditions for the ozone concentration and the optical light path, are sought for. Besides of the inherent difficulty to prepare ozone for comparison and absolute intensity measurements, some of the discrepancies are certainly due to the use of different lines and spectral regions. In this article we thus try to investigate
70 the consistency of the $5 \mu\text{m}$ data with the $10 \mu\text{m}$ region: i) globally, as a function of the vibrational band and ii) locally, as a function of few individual transitions, using atmospheric observations from a ground based FTIR instrument. The present study

thus is part of a greater effort of using ground based atmospheric remote sensing studies for improving the spectroscopic databases, such as has been demonstrated for the case of water [30], for example.

Our comparisons are done using the currently available data from the three different spectroscopic databases GEISA [31], HITRAN [32] and S&MPO [33], which allows one to investigate differences and possible inconsistencies. Due to the complexity of linking column measurements to spectroscopic data, a simple method is introduced that permits to derive characteristic spectroscopic parameters for each spectral window and database. Based on comparisons of these representative values, differences in atmospheric retrievals can be traced back to differences in the spectroscopic databases. The comparison of databases in each of the spectral regions is thus another goal of this article, which is structured as follows: We begin with a description of the experimental tools, the spectroscopic data and the retrieval procedure. The sensitivity of ozone columns on different spectroscopic parameters in the 10 μm range is then discussed and we conclude with a detailed comparison of ozone data in the spectroscopic databases in the light of our measurements.

2. Experimental setup and data

2.1. Observation site and instrumental description

Atmospheric observations were performed using the Paris ground-based Fourier transform spectrometer (FTS-Paris). This instrument is operated by the SMILE/LERMA² team and is part of the QualAir air quality research station of Université Pierre et Marie Curie (UPMC). The instrument is located in downtown Paris on the UPMC campus (48°50'N, 2°21'E at 65 m a.s.l). A detailed description of the system can be found elsewhere [34]. Here, we just give a short description and technical key data are summarized in Table 1.

²SMILE is the French acronym for "Molecular Spectroscopy and Laser Instrumentation for the Environment"

2.2. Data acquisition

The spectra recorded by ground-based FTIR contain rovibrational signatures of atmospheric species in the characteristic fingerprint and group frequency regions (3 – 10 μm , extendable). To optimize the signal-to-noise ratio in the spectral domains of the ozone signals, appropriate combinations of optical filters and detectors have been chosen (see Table 1). Data were acquired during daytime and only clear sky spectra have been kept for the analysis. In order to optimize the signal-to-noise ratio, the evaluation has further been restricted to spectra that were obtained around noon (10:00 – 14:00). Here we present data that were acquired at six days in 2013. An overview of the spectroscopic data and windows is given in Figure 1.

2.3. Spectroscopic Data

Data were taken from the latest versions of the three databases GEISA, HITRAN and S&MPO (G11, H12 and S15, hereafter). The origin of these data and the available parameters are specified for each spectral region separately. Note that S&MPO does not keep track of changes of the available data. The data used here represent a snapshot made in December 2015 using the `smo.univ-reims.fr` website. All of the databases essentially provide spectroscopic data concerning the main and singly substituted ozone species: $^{16}\text{O}_3$, $^{16}\text{O}^{16}\text{O}^{18}\text{O}$, $^{16}\text{O}^{18}\text{O}^{16}\text{O}$, $^{16}\text{O}^{16}\text{O}^{17}\text{O}$, $^{16}\text{O}^{17}\text{O}^{16}\text{O}$ (or 666, 668, 686, 667, 676 in shorthand notation). While the singly substituted isotopologues except for $^{16}\text{O}^{18}\text{O}^{16}\text{O}$ have been included into the database only at the end of 2015, S15 also includes the pure $^{18}\text{O}_3$ isotopologue and gives intensities on a per species' basis. H12 and G11 assume that the above molecules occur in fixed proportions of 0.992901, 0.00398194, 0.00199097, 0.000734 and 0.00370 respectively [24]. These relative abundance factors are therefore already incorporated into intensities given in the databases [35], which is also the convention assumed by the retrieval software. The above relative values are based on the isotope abundance of standard mean ocean water (SMOW) [36]. By taking these proportions one evidently ignores the strong and variable isotopic enrichments that actually occur in atmospheric ozone [37–39]. Nevertheless, the assumption is made throughout and will have no significant impact on the total ozone column values.

Another notable difference between databases is the kind of spectroscopic parameters that are provided. Table 2 gives a comparison of these data. The lack of the air
 130 temperature coefficient n_{air} of the broadened half width in S&MPO needs to be pointed
 out here as a possible obstacle for atmospheric applications. Throughout the paper we
 have assumed the constant value $n_{\text{air}} = 0.76$ in doing retrievals with S15. As far as
 line intensities of $^{16}\text{O}_3$ are concerned, data from the $\{\nu_1, \nu_3\}$ fundamentals at $10\ \mu\text{m}$
 in H12 and S15 are due to dipole moments of Flaud *et al.* [16] (see Ref. [40]), while
 135 corresponding values in G11 are referenced to Ref. [14]. The $5\ \mu\text{m}$ cold band transi-
 tions of $^{16}\text{O}_3$ in H12 stem from the calculation published in Ref. [41] and are scaled by
 a normalization factor of $1/(1.04)$ [40]. The same data in G11 result from the work in
 Ref. [42], while corresponding transitions in S15 come from calculations of GSMA in
 Reims [43].

140 The $10\ \mu\text{m}$ region comprises the fundamental of the dyad formed by the normal
 stretch modes ν_1 and ν_3 , but also harmonic and hot band transitions. We note that
 normal mode frequencies are 1103.08 and $1041.89\ \text{cm}^{-1}$ for ν_1 and ν_3 , respectively and
 that the ν_3 band has the highest band intensity of the normal modes. Altogether 1157
 lines in the selected window $10-1$ at and above our threshold intensity of $10^{-23}\ \text{cm}$ are
 145 reported in HITRAN.

The threshold, which was not applied to the retrieval that included all available
 lines in the databases, corresponds to 2 to 3 times our limit of detection (LOD). These
 lines belong to different vibrational transitions. Using the Boltzmann factors

$$F_B(T) = \exp(-c_2 E''/T), \quad (1)$$

defined by the lower state energy E'' , temperature T and second radiation constant
 150 $c_2 = 1.4387770(13)\ \text{K cm}^1$, one readily estimates that only ground state $\{001, 100\} \leftarrow$
 000 and hot band transitions from the first excited states $010, 001$ and 100 need to be
 considered at $296\ \text{K}$, if contributions of less than $0.2\ \%$ to the total intensity are ne-
 glected. The restriction to the above transitions should even be more accurate, because
 temperatures in the ozone layer are much lower.

155 2.3.1. Retrieval strategy

Ozone total columns

$$C_{O_3} = \int n_{O_3}(z) dz \quad (2)$$

where $n_{O_3}(z)$ is the ozone number density along the light path with coordinate z , are retrieved using the PROFILE FIT (PROFFIT) algorithm developed by Hase et al. [44].

The radiative algorithm (forward model) is based on the Beer-Lambert law and calculates the atmospheric absorbance, which is compared and fitted to the measured spectrum using a least squares minimization method. Input parameters for the forward modeling are: spectroscopic line parameters (position, intensity, pressure line shift, pressure broadening parameters) from the spectroscopic databases; atmospheric pressure and temperature vertical profiles from NOAA (see <http://www.ncep.noaa.gov>); a priori vertical Volume Mixing Ratio (VMR) profiles of all of the studied species, the H_2O continuum [45], and the instrument line shape [46–48], which is regularly monitored using sealed and non-sealed gas cells filled with HCl, HBr and N_2O . The inversion model supports both optimal estimation and Twomey-Tikhonov constraints and is able to perform the retrieval in $\log(\text{VMR})$ space for strong variability in an optimal manner. Columns are measured along the light path but are usually converted to vertical columns, assuming spherical symmetry of the atmosphere. In this paper we do not need to be concerned with the difference between these two and might for simplicity assume that the absorption occurs along the vertical direction.

In the spectral regions corresponding to the fundamental $\{\nu_1, \nu_3\}$ bands at $10 \mu\text{m}$, one window (10–1) consisting out of 5 sub-windows was used and in the region of the $\nu_1 + \nu_3$ combination bands at $5 \mu\text{m}$ four different windows (5–1 through 5–4) with between 4 and 7 sub or micro-windows were employed in the analysis. The windows and the micro-windows are detailed in Table 3 and Figure 2 gives a graphical representation of the acquired spectra. Micro-windows in both spectral ranges were chosen in order to minimizing contributions from interfering species, which mainly are H_2O , CO_2 , N_2O , CO and OCS . Their contributions were determined in separate retrievals using appropriate spectral windows. The ozone columns have then be retrieved using a daily mean vertical profile of the interferer substances.

We note that the 10 μm range has been used intensively for the retrieval of ozone
 185 in both space missions (for instance MIPAS [49] and IASI [22]) and ground based re-
 mote sensing (NDACC [4, 50]). O_3 columns retrieved from window 10-1 are therefore
 considered as reference values.

Figure 1: Overview of spectral regions and micro-windows used for the ozone retrieval. Top – 5 μm win-
 dows, bottom – 10 μm window. Red, black and blue traces respectively indicate measured and fitted spectrum
 as well as the residual signal. See Table 3 for micro-window boundaries and supplemental information.

3. Parameter Sensitivity Study

3.1. Atmospheric conditions

190 Figure 2 gives an overview of the typical retrieved ozone profile and atmospheric
 measurement conditions. In the altitude range from 0 to 34 km, ozone number densi-
 ties vary between 0.9 and $4 \cdot 10^{12} \text{ cm}^{-3}$, with the maximum reached at circa 23 km of
 altitude. Above 34 km, ozone concentrations decrease exponentially at a rate of about
 one decade per 7 km. Temperatures at the ozone maximum are on the order of 220 K
 195 and the column averaged ozone temperature

$$\bar{T}_{\text{O}_3} = \frac{\int dz T(z) n_{\text{O}_3}(z)}{\int dz n_{\text{O}_3}(z)} \quad (3)$$

takes the value of 235 K. Most of the ozone signal thus comes from altitudes below

Figure 2: Typical ozone and temperature profiles of measurements in 2013 (left panel). Right panel shows $\beta/(1 + \beta)$, which is an indicator for the contribution of the pressure broadened halfwidth to the overall line width.

34 km. The Voigt shape parameter

$$\beta = \gamma_L / \gamma_G \quad (4)$$

where γ_L and γ_G are Lorentzian and Gaussian halfwidths, respectively, can be used to quantify the importance of pressure broadening on the line shape. The function $\beta/(1 + \beta)$, in particular, is a measure for the contribution of pressure broadening to the total linewidth. It takes a value of 39 % at 34 km, and increases steadily with decreasing altitude, indicating that pressure broadening is dominating in the altitude range somewhat below 34 km.

3.2. Sensitivity study at 10 μm

In order to identify spectroscopic requirements and understand differences between spectroscopic databases, we have determined the sensitivity of the ozone column C_{O_3} to the intensity (S), air-broadened half width (γ_{air}), its temperature coefficient (n_{air}) and the lower state energy (E'') expressed as equivalent wavenumber.

Line shape parameters beyond the Voigt profile due to Dicke narrowing, speed effects (velocity changing collisions and speed dependence of pressure broadening and shifting) and due to line-mixing are not yet routinely provided by the databases. We

therefore don't discuss these effects here. Actually, non-Voigt effects on isolated ozone lines can be safely neglected, since their impact on the total ozone column is 0.1 % or less [51]. However, neglecting line-mixing effects can bias the ozone total column retrieval in the 10 μm range by up to 2 % [52], but in section 4 we will present evidence that if any, the impact of line-mixing on total ozone column values in our study is likely significantly smaller ($< 1\%$).

We here define the sensitivity coefficient α as the proportionality factor between relative changes of C_{O_3} due to relative changes of the respective parameter $x \in (S, \gamma_{\text{air}}, n_{\text{air}}, E'')$, i.e.:

$$\frac{\Delta C_{\text{O}_3}}{C_{\text{O}_3}} = \alpha(x) \frac{\Delta x}{x}. \quad (5)$$

Related definitions, such as the band specific sensitivity $\alpha_l(x)$ and corresponding weight factors w_l are given in Appendix A.1.

Table 4 gives intensity weights w_l in the 10 μm window for the bands that account for more than 99 % of the absorbed intensity at $T = 235\text{ K}$. It indicates that the fundamentals $\{001, 100\} \leftarrow 000$ should contribute about 93 % to the retrieved signal. The second most important transition is the hot band from the $\nu_2 = 1$ lower state ($\sim 5\%$).

Note that calculated weights are only approximate. In the atmosphere, radiation transfer based on the Beer-Lambert law

$$I(\nu) = I_0(\nu) \exp \left(- \int n_{\text{O}_3}(z) \sum_l S_l(z) g_l(\nu, z) dz \right) \quad (6)$$

(here given for a single absorber with multiple absorption lines l of line shape $g_l(\nu, z)$ and a vertical number density profile $n_{\text{O}_3}(z)$ and neglecting the apparatus function) will introduce a non-linearity, because the exponential preferentially damps stronger transitions. On the contrary, the averaging in eqs. (A.3) and (A.2) which is used to determine the contribution of individual bands to the overall signal in Table 4, does not take this dampening into account and must therefore overestimate strong absorption lines.

3.2.1. Sensitivity on line intensity

The optical density is defined as the negative of the exponent in the Beer-Lambert law (eq. (6)):

$$\tau(\nu) = \ln \left(\frac{I_0(\nu)}{I(\nu)} \right) = \int n_{O_3}(z) \sum_l S_l(z) g_l(\nu, z) dz. \quad (7)$$

τ is thus linear in both, S and n_{O_3} . Since the total ozone column (eq. (2)) is also linear in n_{O_3} , but independent of S , the line intensity and C_{O_3} are directly anti-correlated and $\alpha(S) = -1$. This value (-0.98) is indeed obtained for the sum of all bands (see Table 4). For individual bands, however, some deviation from the average is observed and values between 0.8 and 1.8 times of the average are obtained. As discussed before, the non-linearity of eq. (6) and the simplifying assumption of an isothermal atmosphere contribute to this difference. The ν_3 fundamental, in particular, shows a sensitivity $|\alpha(S)| < 1$, which is in line with the expectation that the band with the strongest transitions should have a sensitivity weaker than average. Evidently, there must be other bands that compensate for this deficit, explaining the relatively large value for the hot band from the $\nu_2 = 1$ lower state.

For the discussion of the sensitivity to other parameters (γ_{air} , n_{air}), ratios of α -values are also presented in Table 4.

3.2.2. Sensitivity on pressure broadening coefficient

Inspection of Table 4 reveals that $|\alpha(\gamma_{air})|$ is roughly three to six times smaller than $|\alpha(S)|$. Intensity corrected values $|\alpha(\gamma_{air})/\alpha(S)|$ are between 0.15 and 0.3. However, a striking feature in Table 4 is the opposite sign of $\alpha(\gamma_{air})$ for $001 \leftarrow 000$ as compared to the other vibrational bands. As shown in a simple numerical simulation in Appendix A.2, this is caused by line shape biases which are different for high and low peak center optical densities τ_0 , which must affect the strong $001 \leftarrow 000$ band differently than the others.

An empirical correlation between line intensity and peak center optical density τ_0 has been derived from the atmospheric spectra (Fig. 1) using some lines around 992 and 1006 cm^{-1} . By comparison with the characteristic intensity of each band (obtained as intensity weighted average, see supplementary material), $\tau_0 \simeq 9$ and $\alpha(\gamma_{air}) < 0$ is

estimated for the 001←000 fundamental, whereas the range $0.08 \leq \tau_0 \leq 0.6$ corresponding to $\alpha(\gamma_{air}) \simeq +0.4$ is derived for the remaining weak bands (see Fig. A.7e).

Due to the simplifying approach of characterizing the bands by their weighted intensity and due to using an empirical correlation and ignoring the vertical atmospheric structure, it is not surprising that the agreement between the simple modeling and our observations is only semi-quantitative and that the sensitivity for the ν_3 fundamental is overestimated by our approach. Nevertheless, the sign change with intensity as well as the sensitivity coefficient $|\alpha(\gamma_{air})/\alpha(S)| \simeq 0.3$ in Table 4 for the weak band transitions is quite well reproduced by the simple estimation. The modeling results thus confirm our interpretation of the sensitivity coefficient being a fitting artefact due to biases in γ_{air} .

3.2.3. Sensitivity on temperature coefficient of pressure broadening

The temperature coefficient n_{air} determines the temperature dependence of the pressure broadening coefficient

$$\gamma_{air}(T) = \gamma_{air}(296 \text{ K}) \left(\frac{296 \text{ K}}{T} \right)^{n_{air}}. \quad (8)$$

Biases in n_{air} are therefore directly linked to biases in γ_{air} , especially if measurements or observations are made at one particular temperature. We therefore expect that there is a strong correlation between the sensitivity coefficients of these two parameters. The ratio $\alpha(\gamma_{air})/\alpha(n_{air})$ for an isothermal atmosphere might be derived from the above eq. (8) by taking the derivative of γ_{air} with respect to n_{air} and keeping the lowest order correction (note that we drop the index *air* for the moment)

$$\begin{aligned} \frac{\Delta\gamma}{\gamma}(T) &= \left(\frac{296 \text{ K}}{T} \right)^{\Delta n} - 1 \\ &\simeq n \ln \left(\frac{296 \text{ K}}{T} \right) \frac{\Delta n}{n}. \end{aligned} \quad (9)$$

which directly leads to

$$\frac{\alpha(\gamma)}{\alpha(n)} \simeq n^{-1} \ln^{-1} \left(\frac{296 \text{ K}}{T} \right). \quad (10)$$

For the two 011 ← 010 and 002 ← 001 hot bands and the ν_1 fundamental, the databases give ranges between 0.72 and 0.80 (H12) or 0.73 and 0.76 (G11) for the

intensity weighted temperature coefficients n_{air} (see supplementary material). Using our characteristic ozone temperature from eq. (3) of 235 K and following eq. (10), these values correspond to sensitivity ratios $\alpha(\gamma_{air})/\alpha(n_{air})$ between 5.4 and 6.1 (H12) and between 5.7 and 5.9 (G11). These ranges are very consistent with the observed range from 5.3 to 5.6 defined by the two strongest of the weak transitions in Table 4. Given the large measurement uncertainties, especially for the weak bands that contribute by only about 1 % to the overall absorption signal, this agreement might be somewhat accidental, as indicated by the value of 4.3 for the ν_3 hot band, which is somewhat below the expected range.

3.2.4. Sensitivity on lower state energy

The main impact of the lower state energy E'' (or its equivalent wavenumber value) on the intensity, and thus on the ozone column, is via the Boltzmann factor $F_B(T)$ in eq. (1) [see 35, for example]. It is thus evident that

$$\frac{\Delta C_{O_3}}{C_{O_3}} = -\frac{\Delta S}{S} = \frac{c_2}{T} \Delta E''. \quad (11)$$

At 235 K, $c_2/T = 6.1 \cdot 10^{-3}$ cm and due to lower state energies being usually known better than 10^{-2} cm⁻¹, the uncertainties in E'' have a negligible ($< 10^{-4}$) impact on the (relative) uncertainty of the column measurements.

4. Database comparison

4.1. 10 μ m region

Fig. 3 shows retrieval results for total ozone column densities from the 10 μ m region at Paris during six summer days around noon using the G11, H12 and S15 databases. The left panel demonstrates that column density retrievals give similar values when either of the three databases is used. Within one four-hour observation period, ozone columns are between 8.3 and $9.7 \cdot 10^{18}$ cm⁻² and vary only on the 1 % scale ($\sim 0.1 \cdot 10^{18}$ cm⁻²). However the data reveal a small systematic bias between the three databases. Columns retrieved using the H12 database are always higher than columns from S15 and G11, and retrievals using G11 always give the lowest results. Indeed,

the right panel of Fig. 3 well illustrates that the respective offsets of -0.604% and -0.288% between the G11 and H12 and the S15 and H12 databases are quite significant. The scatter ($\sigma = 0.008\%$, $N = 95$ for G11 and $\sigma = 0.028\%$, $N = 95$ for S15) is comparatively small.

Figure 3: Total ozone column densities C_{O_3} around noon during six measurement days in summer 2013 from retrievals in the $10\ \mu\text{m}$ window (10–1). Left panel shows absolute values retrieved with H12 (squares), G11 (circles) and S15 (triangles) spectroscopic data. Right panel gives the relative deviation of retrieval results in percent. Circles and triangles correspond to results with unmodified G11 and S15 spectroscopic data, respectively. Squares are differences when bandwise corrections are applied to ^{16}O and ^{18}O -containing ozone in G11. Diamonds indicate deviations when ^{17}O data from H12 are added to the modified G11 data.

Most of the bias between G11 and H12 is due to systematic differences in the average spectral parameters. Table 5 demonstrates that some intensity weighted spectral parameters, and even intensity values, differ by several percent. If S , γ_{air} and n_{air} in G11 are thus adjusted bandwise by the ratio $x_{\text{H12}}/x_{\text{G11}}$ to compensate for these differences, the relative bias is reduced to a value of only -0.138% ($\sigma = 0.005\%$, $N = 95$), as shown in the right panel of Fig. 3. Interestingly, correcting for systematic biases between H12 and S15 using the same method does not improve the relative deviation in the column values; at the same time the dispersion of the data is significantly reduced. The results are not shown in Fig. 3, but we get a -0.323% offset with a $\sigma = 0.007\%$ dispersion when we apply the standard correction procedure based on the weighted averages in Table 5. The reduction of the dispersion is mainly due to the difference in γ_{air} . As a matter of fact, correcting for differences in the weighted averages of γ_{air} alone results in an offset of -0.332% with a 0.006% scatter. This is quite similar to

using the actual values of γ_{air} in H12 with intensities of S15. In this case the offset is -0.227% with a standard deviation of $\sigma = 0.007\%$. The comparison using the three databases also shows that using γ_{air} from either H12 or G11 leads to a small dispersion in the retrieved columns, whereas the dispersion is about four times higher when S15 is compared to H12. Note, that relative differences in weighted γ_{air} are also four times higher when we compare the ν_3 transition of the main isotope in S15 and G11 with respect to the corresponding values in H12 (see Table 5).

As can also be inferred from the sensitivity coefficients in Table 4, a global correction of about 0.21% , 1.15% and 1.10% applied to the respective values of S , γ_{air} and n_{air} in G11, irrespective of the vibrational band, would only account for a small fraction of the observed total column difference and it is essential to consider vibrational states individually. The need for bandwise correction is thus evident and this is also clear from direct inspection of Table 5, which shows strong differences between the databases concerning hot band transitions: hot band intensities of $^{16}\text{O}_3$ in H12 are 1.6 and 4% lower than in G11, for example. This, and the fact that fundamentals of the ^{18}O containing isotopomers also deviate by about 4% between the two databases, possibly indicates that intensities of the hot bands were globally changed in the 2000 to 2004 update of H12, whereas most of the G11 data remained unchanged. Depending on isotopes or transitions, differences in γ_{air} can also be quite sizable and reach values of up to 13% (Table 5). Some of the remaining discrepancy between ozone columns derived from G11 and H12 spectral parameters is due to the complete lack of ^{17}O containing ozone in the $10\ \mu\text{m}$ region in G11. If also taken into account, the bias between databases drops well below 1‰ (see right panel of Fig. 3). Interestingly, this good agreement between the atmospheric radiation transfer modeling and the global bandwise analysis can only be obtained in the comparison between G11 and H12 databases. Applying the same correction procedures to the S15 data does not remove the -3‰ offset between the column values from H12 and S15. The reasons for this difference are detailed just below.

The lower right panel of Fig. 4, which compares H12 with G11, shows that most of the intense bands in the $10\ \mu\text{m}$ region differ by a constant value (either 0 or 4%). Only the $011 \leftarrow 010$ hot band, which contributes about 5% to the overall absorption

Figure 4: Relative deviation of intensities of individual $^{16}\text{O}_3$ transitions between H12 and G11 databases as a function of line position (top) and of intensity $S(296\text{ K}) \geq 10^{-23}\text{ cm}$ (bottom). Top: individual windows (5-1 to 5-4) in the $5\text{ }\mu\text{m}$ range are indicated by shadows. Bottom: Left panel $5\text{ }\mu\text{m}$, right panel $10\text{ }\mu\text{m}$ data. Line data common to the two databases and corresponding to the four most intense bands (with weights given in the legends) are shown.

shows some scatter and a slight negative correlation in this wavelength region. The presence of such a correlation introduces a bias in the database comparison based on intensity weighted averages (see Appendix B, for example). These correlations are stronger when we compare H12 to S15. The lower right panel of Fig. 5 shows that a positive correlation even exists in the most intense transitions of the ν_3 band. From

Figure 5: Relative deviation of intensities of individual $^{16}\text{O}_3$ transitions between H12 and S15 databases as a function of line position (top) and of intensity $S(296\text{ K}) \geq 10^{-23}\text{ cm}$ (bottom). Top: individual windows (5–1 to 5–4) in the $5\text{ }\mu\text{m}$ range are indicated by shadows. Bottom: Left panel $5\text{ }\mu\text{m}$, right panel $10\text{ }\mu\text{m}$ data. Line data common to the two databases and corresponding to the four most intense bands (with weights given in the legends) are shown.

a linear fit of $\Delta S/S$ vs. $S(235\text{ K})$ in the range $S > 10^{-21}\text{ cm}$ on transitions in the ν_3 band of the main isotope, we derive a slope of $+3.6 \cdot 10^{17}\text{ cm}^{-1}$ and inspection of the H12 database shows that $2[E(S^3)/E(S^2) - E(S^2)/E(S)] = 7.9 \cdot 10^{-21}\text{ cm}$ (for further details see Appendix B). According to eq. (B.6), this results in an overestimation of the adjusted intensities by about 0.3 %. Ozone columns will thus be underestimated by the same relative amount, when adjusted intensity values are used and this corresponds exactly to the observed difference between retrievals based on S15 and H12 displayed in Fig. 3.

4.2. 5 μm region

Figure 6: Total ozone column densities C_{O_3} from the 5 μm windows 5–1 to 5–4 as relative deviation with respect to the retrieval from the 10 μm window (10–1). Panels from left to right show results for the H12, G11 and S15 database, respectively. Individual 5 μm windows are indicated by symbol shades.

Column densities from the 5 μm windows are represented in Fig. 6 as relative deviation from the result in the 10 μm window. Independent of the database, the results from the two wavelength regions are coherent to better than $\pm 3\%$. Averages over individual windows are within -1.0 and $+1.6\%$ for H12, within -1.0 and -2.3% for G11 and within -0.3 and $+0.5\%$ for S15. While G11 data thus give a consistent negative offset of about $(-1.9 \pm 0.6)\%$ (1σ dispersion of window averages) with little dispersion and while S15 has an insignificant offset with an even smaller dispersion of $(0.2 \pm 0.4)\%$, the H12 data have a positive offset of $(1.4 \pm 0.4)\%$ for windows 5–2 through 5–4. The 5–1 window, which is dominated by transitions belonging to the P -branch of the $\nu_1 + \nu_3$ band, however is not consistent with this positive shift and shows an offset of -1.0% . Note that the dispersion within each window (1σ , $N = 93$) is in the 0.3 to 0.4% range. This single intra-window dispersion is independent of the window and the database used and thus merely reflects measurement uncertainties.

We point out that our atmospherically observed offset of $+1.4\%$ between 5 and 10 μm regions when using H12 is in full agreement with a recent laboratory study [27]. The laboratory derived intensities deviate from H12 by (-1.96 ± 0.29) and $(-0.34 \pm 0.11)\%$ at 5 and 10 μm , respectively. This implies $C_{O_3}^{H12}(5 \mu\text{m})/C_{O_3}^{H12}(10 \mu\text{m}) = (+1.6 \pm 0.3)\%$, where the 1σ uncertainty is derived from the propagation of the sta-

tistically derived uncertainty of the individual averages at 5 and 10 μm . The comparison with this measurement and the fact that line-mixing does not measurably change
395 total ozone columns from the 5 μm range under atmospheric conditions [52, see Table 1], let us conclude that line-mixing impacts total ozone columns from the 10 μm region (window 10–1) by an amount less than the dispersion of our measurements. A similar conclusion must be drawn from the comparison with the slightly higher value
 $C_{\text{O}_3}^{\text{H12}}(5 \mu\text{m})/C_{\text{O}_3}^{\text{H12}}(10 \mu\text{m}) = (+2.1 \pm 0.3) \%$ derived in another laboratory study under
400 high pressure conditions (0.3 – 1 bar), where line-mixing effects have been taken into account in the analysis [52]. This high degree of agreement with both laboratory experiments implies that the effect of line-mixing on the derived total ozone column densities is small and likely less than about 0.7 %. The full agreement between retrieval results from all windows within the scatter of about 0.4 % when S15 is used
405 (right panel of Fig. 6) indeed provides very strong support for line-mixing effects actually being smaller than 0.4 %. Anyway, they are smaller than most of the effects that we are about to discuss in the following.

The differences of about 3.5 % (windows 5–2 through 5–4) between the G11 and H12 databases can be easily understood on the background of our previous analysis
410 and discussion concerning the 10 μm region. Calculation of intensity weighted spectral parameters at 235 K shows that in each of the windows most of the absorbed intensity is due to the 101 $\leftarrow$ 000 band. This band has a roughly 3 (5–1) to 4 % (5–2 to 5–4) higher weighted intensity in G11 than in H12 (see Table 6), implying that the column densities must be correspondingly lower. From this $\sim 4 \%$ correction, the 0.6 % difference in
415 the 10 μm region must be subtracted. The resulting shift in $C_{\text{O}_3}(5 \mu\text{m})/C_{\text{O}_3}(10 \mu\text{m})$ of 3.4 % is fully consistent with the atmospheric observation in Fig. 6. We note that intensities of these overtone and combination bands are sufficiently weak for non-linear absorption effects, such as observed in the ν_3 fundamental at 10 μm , being of little importance.

420 Table 6 further shows that the ratio of ozone columns derived from the two databases at 5 μm $C_{\text{O}_3}^{\text{H12}}(5 \mu\text{m})/C_{\text{O}_3}^{\text{G11}}(5 \mu\text{m})$ cannot be consistent over all windows at the accuracy level of 1 %. The weighted average analysis confirms that the column ratio $C_{\text{O}_3}^{\text{H12}}(5 \mu\text{m})/C_{\text{O}_3}^{\text{G11}}(5 \mu\text{m})$ is lower in the 5–1 window than in the others. Because results from the

G11 database are consistent over all four windows, we suspect that the problem is
 425 linked to the spectroscopic data in H12. However, the simplified database comparison
 in Table 6 gives a difference of only 1.4 % and rests below the observed discrepancy of
 about 2 to 2.5 %. These database differences are further corroborated by the excellent
 agreement found in the S15 based retrievals.

As an aside we note here that the $111 \leftarrow 010$ hot band has identical intensity entries
 430 in all three different databases. This becomes evident from Fig. 5, but is also reflected
 in the corresponding entries in Table 6, which are all identical zero.

The large intensity dependent differences in line strengths of $2\nu_1$, $2\nu_3$ and $\nu_1 + \nu_3$
 band transitions between the G11 and H12 databases (see left panel of Fig. 4) prevent
 intensity weighted averages to be used for globally rescaling one database with respect
 435 to the other in order to resolve observed discrepancies in the $5 \mu\text{m}$ region. The col-
 umn biases associated with a weighted intensity correction, that are obtained from the
 procedure described in section 4.1 are around 1.4 %. It thus seems that this particular
 spectral region requires new experimental and theoretical studies to be undertaken. The
 high consistency of the S15 based retrievals possibly indicates that the S&MPO (S15)
 440 database presently is the most adequate to use for retrieving ozone from the 5 and 10
 μm regions, and that the underlying data and spectroscopic analysis already provide
 the desired level of accuracy of better than 1 %. But so far these data have not been
 published in the literature. It must also be kept in mind that our study cannot assess
 the absolute accuracy of the spectroscopic data and since our observations are based
 445 on lines from very restricted spectral ranges (see Fig. 1), little can be said about data
 quality concerning transitions outside the observational windows.

5. Conclusion and Outlook

We have compared ozone spectroscopic data in the 5 and $10 \mu\text{m}$ spectral regions
 from different databases and confronted them with ground based atmospheric spectra,
 450 acquired with the high-resolution FTS-Paris instrument. In order to clearly attribute
 differences in retrieved ozone columns to differences in the spectroscopic databases,
 we have also performed direct database comparisons restricted to the observational

windows, using intensity weighted averages of the chief spectroscopic parameters.

Using the atmospheric spectra, a complete sensitivity analysis of the four spectro-
455 scopic parameters intensity (S), air-broadening half width (γ_{air}), its temperature coef-
ficient (n_{air}) and the lower state energy (E'') has been performed in the $10\ \mu\text{m}$ region.
Relative uncertainties of these parameters belonging to transitions in the ν_3 fundamen-
tal band impact on the total ozone columns with respective of weights $-1 : -0.15 :$
 -0.05 , for S , γ_{air} and n_{air} . For transitions belonging to weaker bands in the same
460 region, sensitivity coefficients for S , γ_{air} and n_{air} scale as $-1 : +0.29 : +0.055$. The
observed sensitivity coefficients have been confirmed by theoretical analysis and nu-
merical simulations. Current database uncertainties in E'' do not affect retrievals and
can be neglected. The derived sensitivity coefficients might guide further studies that
aim at improving on the uncertainty of total ozone column retrievals in that region.

465 The three databases HITRAN, GEISA and S&MPO have been characterized with
respect to their utility for atmospheric retrievals. Using the spectroscopic data in the
 $991.25 - 1013.19\ \text{cm}^{-1}$ window range, total ozone column retrievals with the three
databases gave results that agreed to clearly better than 1 %. Much of the difference
is due to slight differences in the spectroscopic data and, in case of in the GEISA
470 database, the lack of ^{17}O -containing ozone. This degree of agreement is confirmed by
direct comparison of spectroscopic databases, using intensity weighted averages of the
spectroscopic parameters.

Deviations between the databases in the $5\ \mu\text{m}$ region are larger, however. Ozone
columns derived in that wavelength range differ by about 4 %, which is likely due to
475 a global adjustment of line intensities [18] in the HITRAN database in 2004, which
has only partially been adopted in the GEISA database. Nevertheless, each of the three
databases gives total ozone columns at $5\ \mu\text{m}$ that generally agree within $\pm 2\%$ with
the results obtained at $10\ \mu\text{m}$. Retrievals using the S&MPO data show an even better
agreement within less than $\pm 1\%$, both between the 5 and $10\ \mu\text{m}$ regions and within the
480 $5\ \mu\text{m}$ region itself.

Importantly, all four windows in the $5\ \mu\text{m}$ region yield consistent ozone columns
when we use parameters from the GEISA or S&MPO databases. This is not the case
when parameters are taken from HITRAN. Employing HITRAN parameters, one of

the windows ($2070.90 - 2084.64 \text{ cm}^{-1}$), mostly containing *P*-branch transitions from
 485 the $\nu_1 + \nu_3$ combination band in the $5 \mu\text{m}$ region results in ozone columns that are significantly lower ($1.5 - 3.0 \%$) than the ones obtained from the other three windows. This striking difference between databases is corroborated by direct comparison of the intensity weighted average intensities in the four windows. While average intensities between HITRAN and GEISA databases differ by 4.1% in the three coherent windows, 490 they differ by only 2.7% in the particular window between 2070.90 and 2084.64 cm^{-1} . The inferred difference of 1.4% is close to the observed discrepancy, which thus confirms that the observed mismatch is due to the ozone spectroscopic data in the two databases and not linked to the measurement process or the retrieval procedure. This fact is further corroborated by the excellent consistency of results when either GEISA 495 or S&MPO are used for the retrieval.

While the comparison in the $10 \mu\text{m}$ region has shown that all databases yield very consistent results at a high level of precision ($< 1 \%$), the detailed analysis of the $5 \mu\text{m}$ region shows that a similar precision level has not yet been reached there. Only the S&MPO database gives entirely consistent results at the 1% level. Thus, further laboratory studies targetting at the $5 \mu\text{m}$ and other spectral regions are required. So are 500 new theoretical calculations [10] and validation procedures for incorporating new line parameter data into the databases.

With the availability of more and more spectroscopic databases or linelists, the simple method of comparing intensity weighted spectroscopic parameter averages may 505 provide an interesting tool for analyzing these databases for consistency and thus for identifying critical regions for remote sensing applications. While the approach avoids entering into the tedious work of analyzing individual transitions, it remains to be shown that its application is useful for the remote sensing of molecules other than ozone.

510 **Appendix A. Sensitivity**

Appendix A.1. Band specific sensitivity coefficients and intensity weights

In this appendix, definitions for the band specific sensitivity coefficients and intensity weights are given. We first define the band specific sensitivity coefficient $\alpha_I(x)$

$$\alpha_I(x) = \frac{1}{w_I} \left(\frac{\Delta C_{O_3}}{C_{O_3}} \right) \left/ \left(\frac{\Delta x_I}{x_I} \right) \right. \quad (A.1)$$

where x_I indicates that parameter changes of a rovibrational transition are considered only if this transition belongs to the particular band I . The weight w_I of the vibrational band I is defined as the ratio of the pseudo band intensity $\hat{S}_I$ over the integrated intensity of all rovibrational transitions within the considered window M :

$$w_I = \hat{S}_I / \sum_{j \in M} S_j, \quad (A.2)$$

where the S_j are line strengths of individual rovibrational transitions j . The pseudo band intensity $\hat{S}_I$ corresponds to the total band intensity restricted to transitions within the observational window M , i.e.:

$$\hat{S}_I = \sum_{j \in I \wedge j \in M} S_j. \quad (A.3)$$

Appendix A.2. Simulation of pressure broadening

We assume a Voigt line shape for a molecular transition and simulate molecular absorption in a homogeneous atmosphere. Three parameters are required: the Gaussian (Doppler) width which is described by the HWHM parameter γ_G , the Lorentzian width for the pressure broadening, given by the HWHM parameter $\gamma_L = \gamma_{air} \times p$, and the optical density at peak center τ_0 . In the atmospheric retrieval, widths are determined by temperature and pressure conditions and the corresponding values therefore are fixed in the fitting process. Nevertheless, the Lorentzian width may be off by a bias in γ_{air} . This effect is investigated through fitting a Voigt line profile with a small bias in γ_L (1.02 times the width of the original profile), leading to a non-zero residual and a biased value for the peak area. The results of these simulations are shown in Figures A.7a-c, where transmission curves of the absorption lines and the fit residuals are displayed

for different optical densities τ_0 . As can be seen, the residuals change from a V to a W-shape when increasing τ_0 from 0.1 to 10. For the simulation, the Doppler width has
 535 been fixed to a typical value of $\gamma_G = 0.1 \text{ cm}^{-1}$, but the result is completely independent of the exact value used. It only depends on the shape parameter β (eq. (4)), which was fixed to $\beta = 7$ in Figs. A.7 a-c for matching typical atmospheric conditions.

In Figure A.7 d, a simulated value of $\alpha(\gamma_{air})$ has been calculated by equation (5), using $\Delta x/x = 0.02$ for various combinations of τ_0 and β . In the high pressure limit ($\beta \geq$
 540 10), $\alpha(\gamma_{air})$ becomes independent of the shape parameter. This is expected, because the width is dominated by pressure broadening anyway and a bias in this parameter should have its maximum effect. In the low pressure limit ($\beta \leq 0.1$), one expects that biases in γ_L can be neglected, because the line shape is dominated by Doppler broadening. For weak absorptions $\tau_0 < 1$, $\alpha(\gamma_{air})$ is indeed about 0. At large optical densities however,
 545 $\alpha(\gamma_{air})$ never vanishes because the wings of the Lorentzian have still an impact on the fit far from the line center, even though the HWHM width is completely dominated by the Doppler profile. This wing effect scales linearly with τ_0 and the asymptotical behavior of $\alpha(\gamma_{air})$ is given by the product $\tau_0 \times \beta = \text{const}$. Figures A.7e-g then illustrate for fixed values of β how $\alpha(\gamma_{air})$ varies as a function of the optical density. At high pressures
 550 ($\beta = 7$), it changes from about +0.45 to -1 at $\tau_0 \sim 100$ (Fig. A.7e). At low pressures, the low optical density limit approaches zero and the transition towards negative values shifts towards higher peak absorption values.

These results on $\alpha(\gamma_{air})$ are robust and do only weakly depend on the exact knowledge of γ_{air} : Comparing the fit results of two line profiles biased by 12 and 10 % in γ_{air} ,
 555 respectively, gave a similar difference in retrieved intensities than comparing a line with 2 % bias to the unbiased line. Grey curves in Figures A.7e-g show the results derived from biases offset by ± 10 %, which is deemed a reasonable range for the uncertainty of the published data. Because it is independent on pressure in the $\beta \geq 7$ range which is characteristic for most of the vertical ozone distribution (see section 3.1), $\alpha(\gamma_{air})$
 560 should follow the τ_0 dependency given in Figure A.7e.

Figure A.7: Sensitivity of the column on biases in the γ_{air} parameter from a simple numerical simulation. Panels a through c show Voigt profiles and fit residuals, when γ_{air} is biased by +2% for peak center optical densities τ_0 of 0.1, 1, and 10, respectively. The Gaussian HWHM, and the shape parameter have respectively been fixed to characteristic value of $\gamma_G = 0.1 \text{ cm}^{-1}$ and $\beta = \gamma_L/\gamma_G = 7$. Panel d shows $\alpha(\gamma_{air})$ as a function of the peak absorption τ_0 and the shape parameter γ_L/γ_G . Contour lines are separated by units of 0.1 and the dashed horizontal line indicates $\beta = 7$. Panels e to g then display $\alpha(\gamma_{air})$ as a function of the peak optical density τ_0 for β fixed to values of 7, 1, and 0.01 (red lines). Grey lines indicate in as much the bias of $\alpha(\gamma_{air})$ depends on the absolute value γ_{air} . Shaded regions in panels e-g indicate estimated atmospheric absorption conditions for the asymmetric stretch (ν_3) with $\tau_0 \simeq 9$ on the one hand and the weaker bands ($0.08 \leq \tau_0 \leq 0.6$) on the other hand.

Appendix B. Bias of intensity weighted averages

We have introduced intensity weighted averages as a practical means of direct comparison of spectroscopic parameters in different databases, which introduces an effective cutoff of weak absorption lines. Here we show that correcting values in one database by the ratio of averages between the two databases does not necessarily reproduce the results of the latter in an atmospheric retrieval and thus introduces a bias. This depends on whether the spectroscopic data correlate with the line intensities or not.

We start from the idealizing assumption that each line contributes to the retrieved absorption signal proportional to its line intensity (*ie* we neglect the presence of noise in the atmospheric measurement). The expectation value or mean E of the statistic of

intensities S is defined by

$$E(S) = \frac{1}{N} \sum_{i=1}^N S_i. \quad (\text{B.1})$$

For what follows, we recall that the second and third moments of S are similarly defined as $E(S^2)$ and $E(S^3)$, respectively. Like $E(S)$, these quantities can be easily calculated from the data given in the spectroscopic databases. We assume that the values
575 in the two databases S_H and S_G suffer from small biases with respect to the true distribution of intensity values S :

$$S_H = (1 + a + bS)S \quad (\text{B.2})$$

$$S_G = (1 + c + dS)S \quad (\text{B.3})$$

The coefficients a and c denote relative offsets of the database values with respect to the true values and coefficients b and $d \neq 0$ indicate a linear correlation of the bias with intensity. In this case the ratio R of expectation values is given by

$$\begin{aligned} R &= \frac{E(S_H)}{E(S_G)} = \frac{E((1 + a + bS)S)}{E((1 + c + dS)S)} \\ &\simeq \frac{1 + a}{1 + c} \left(1 + (b - d) \frac{E(S^2)}{E(S)} \right), \end{aligned} \quad (\text{B.4})$$

where the last transformation holds to the degree that terms of second order in the supposedly small deviations a , b , c and d can be neglected. Due to the ratio of weighted averages E_w (eqs. (A.3) and (A.2)) being

$$R_w = \frac{E_w(S_H)}{E_w(S_G)} = R^{-1} \frac{E(S_H^2)}{E(S_G^2)}, \quad (\text{B.5})$$

580 we find that

$$\begin{aligned} R_w/R &= R^{-2} \frac{E(S_H^2)}{E(S_G^2)} \\ &\simeq 1 + 2(b - d) \left(\frac{E(S^3)}{E(S^2)} - \frac{E(S^2)}{E(S)} \right), \end{aligned} \quad (\text{B.6})$$

where in the last step we have once again neglected higher than linear order terms in a , b , c and d . Our bias is thus given by the second term in equation (B.6). Evidently, only if $b \neq d$, we introduce a bias by comparing intensity weighted averages. Note that if

$b = d = 0$, the approximations in eqs. (B.4) and (B.6) become exact and any constant
relative offset between the two databases is inferred without any bias.

A non-zero term ($b - d$) might be inferred as the slope of the linear fit on the $\Delta S/S$
over S data, such as in Fig. 4 and the expression in parantheses can be simply estimated
from using either S_H or S_G for the unknown S . In this way the bias can be determined
and accounted for.

Table 1: Technical data of the Paris-FTS and supporting instruments situated at 48° 50'N, 22° 1'E at 60 m above sea level

<i>FTS</i>	
Instrument Model	IFS 125HR
Max. opt. path difference	258 cm
Spectral resolution	$2.4 \cdot 10^{-3} \text{ cm}^{-1}$
Nominal beam diameter	63.5 mm
Focal length	418 mm
Field stop aperture	1 mm
Instrument vacuum	< 1 Pa
10 μm range	MCT detector KBr beam splitter
Filter transmission (T_F)	$T_F(\text{centre}) > 60 \%$ $T_F(50 \%)$ cut on @ 7.14 μm $T_F(50 \%)$ cut off @ 10.0 μm
4.8 μm range	InSb detector KBr beam splitter
Filter transmission (T_F)	$T_F(\text{centre}) > 60 \%$ $T_F(50 \%)$ cut on at 3.3 μm $T_F(50 \%)$ cut off at 5.0 μm
Duration of acquisition	3 min (2 co-adds)
Acquisition dates	2013-07-19; 2013-07-20; 2013-07-22; 2013-08-16; 2013-08-21; 2013-08-23;
<i>Sun Tracker</i>	
Model	Bruker A547
Pointing precision	1 arc min. (8h)

Table 2: Global comparison of spectroscopic parameters contained in the databases. Two symbols indicate availability of the data in both the 5 and 10 μm windows, respectively. + or – signs mean that values are provided or not provided. Symbols O and F indicate that values have been set to zero or to another fixed standard value, and X signifies that only a few lines have values different from the standard value.

Parameter	Symbol	G11	H12	S15
(Vacuum wavenumber) position	ν	+/+	+/+	+/+
Intensity	$S(296\text{ K})$	+/+	+/+	+/+
Lower-state energy (as wavenumber)	E''	+/+	+/+	+/+
Air (broadened half) width	γ_{air}	+/+	+/+	+/+
Self (broadened half) width	γ_{self}	+/+	+/+	+/+
Air (pressure induced) shift	δ_{air}	O/O	X/X	–/–
Temperature (dependence) exponent (for γ_{air})	n_{air}	F/F	+/+	–/–

Table 3: Spectral windows for the retrieval of total O₃ columns (C_{O₃}) based on the H12 database

Spectral window	Overall spectral range (cm ⁻¹)	Micro-window (cm ⁻¹)	Effective window width (cm ⁻¹)	No of O ₃ lines above threshold / total	Interfering species
10-1	991.25 – 1013.19	991.250 – 993.800	9.440	666: 854/3470	H ₂ O, CO ₂ , C ₂ H ₄
		1001.470 – 1003.040		668: 169/ 421	
		1005.000 – 1006.900		686: 109/ 264	
		1007.470 – 1008.900		667: 5/ 289	
		1011.200 – 1013.190		676: 20/ 143	
5-1	2070.90 – 2084.64	2070.900 – 2071.113	3.193	666: 166/1452	H ₂ O, CO ₂ , CO, OCS
		2079.600 – 2080.500			
		2080.960 – 2081.500			
		2082.500 – 2083.700			
		2084.300 – 2084.640			
5-2	2101.15 – 2109.90	2101.150 – 2102.700	3.110	666: 193/ 577	H ₂ O, CO ₂ , CO, OCS
		2103.800 – 2104.150			
		2104.900 – 2105.040			
5-3	2118.40 – 2127.05	2108.830 – 2109.900	2.300		H ₂ O, CO ₂ , CO, OCS
		2118.400 – 2118.550		666: 105/ 279	
		2119.900 – 2121.000			
		2122.070 – 2122.250			
		2123.140 – 2123.440			
5-4	2130.38 – 2134.90	2125.470 – 2125.700	0.750		H ₂ O, CO ₂ , CO, OCS
		2126.570 – 2126.690			
		2126.830 – 2127.050			
		2130.380 – 2130.490		666: 32/ 133	
		2130.650 – 2130.750			
		2132.440 – 2132.780			
		2134.700 – 2134.900			

Table 4: Sensitivity of the total ozone column CO_3 . α -coefficients (eqs. (5) and (A.1)) indicate the response of CO_3 on global relative changes in line intensity (S), air broadening (γ_{air}) and temperature dependence of the air broadening (n_{air}) as a function of the vibrational band. Weights have been evaluated at $T = 235$ K.

Band	Weight w_I (%)	$\alpha(x)$ or $\alpha_I(x)$			$\alpha(\gamma_{\text{air}})/\alpha(n_{\text{air}})$	$-\alpha(\gamma_{\text{air}})/\alpha(S)$	$-\alpha(n_{\text{air}})/\alpha(S)$
		$x = S$	$x = \gamma_{\text{air}}$	$x = n_{\text{air}}$			
001 $\leftarrow$ 000	91.2	-0.94	-0.152	-0.049	3.3	-0.163	-0.048

Table 6: Relative deviations $\Delta S/S|_{H-G} = (S_{H12}/S_{G11} - 1)$ and $\Delta S/S|_{H-S} = (S_{H12}/S_{S15} - 1)$ of intensity weighted intensities at 235 K in the H12, G11 and S15 databases, restricted to the observational windows 5–1 and 5–2 to 5–4 at 5 μm .

Band	5–1			5–2 to 5–4		
	Weight (%)	$\Delta S/S _{H-G}$ (%)	$\Delta S/S _{H-S}$ (%)	Weight (%)	$\Delta S/S _{H-G}$ (%)	$\Delta S/S _{H-S}$ (%)

Highlights

- Present simple method of spectral database comparison based on weighted intensities
- Analyze ozone spectral data in the 5 and 10 μm ranges using ground based FTIR
- Compare GEISA2011, HITRAN2012 and S&MPO2015 databases using total ozone columns
- All databases are consistent within $\pm 2\%$ when comparing 5 and 10 μm regions
