We used Health Impact Assessment (HIA) to analyze the impact on a given population's health outcomes in terms of all-causes mortality and respiratory and cardiovascular hospitalizations attributable to short-term exposure to particulate matter less than 10 μm diameter (PM$_{10}$) in Bejaia city, for which health effects of air pollution have never been investigated. Two scenarios of PM$_{10}$ reduction were considered: first, a scenario where the PM$_{10}$ annual mean is decreased by 5 μg/m$^3$, and then a scenario where this PM$_{10}$ mean is decreased to 20 μg/m$^3$ (World Health Organization annual air quality guideline (WHO-AQG)). Annual mean level of PM$_{10}$ (81.7 μg/m$^3$) was calculated from objective measurements assessed in situ. Each year, about 4 and 55 deaths could be postponed with the first and the second scenarios successfully. Furthermore, decreasing PM$_{10}$ annual mean by 5 μg/m$^3$ would avoid 5 and 3 respiratory and cardiac hospitalizations, respectively, and not exceeding the PM$_{10}$ WHO-AQG (20 μg/m$^3$) would result in a potential gain of 36 and 23 per 100000 respiratory and cardiac hospitalizations, respectively. Lowering in current levels of PM$_{10}$ has a nonnegligible impact in terms of public health that it is expected to be higher in the case of long-term effects.

1. Introduction

Short-term variations in air pollution have been associated with mortality from various causes in cities all over the world [1–10]. These associations include all-cause mortality [11–15], respiratory mortality [16–20], and cardiac mortality [21–23]. Among air pollutants, suspended particulate matter (PM) is extensively recognized as the most important air pollutant in terms of human health effects considering that many epidemiological studies substantiate significant associations between concentration of PM in the 2 air and adverse health impacts [4, 5, 24–28].

Health impacts assessment of Air Pollution (HIA-AP) is a method encouraged by WHO [29], whose aim is to provide the number of health events that could be prevented by reducing air pollutant levels in the target population. Studies on health impact of air pollution carried out in Algeria are few and limited to Algiers where air pollution is monitored through one air quality (AQ) station. In other regions, like Bejaia city (∼200000 inhabitants) there are no AQ measuring stations. Yet, the constantly increasing number of vehicles, their age (average of 8.5 years), and the tendency to dieselization (52.9% in 2014) are reasons that make Bejaia vehicle fleet a major source of air pollution. In a precedent paper [30], we have presented a descriptive study of the impact of air pollution as assessed through vehicles counts on Bejaia population. We have shown that at the population level exposure to vehicle air pollution is a cause of increased prevalence of respiratory diseases. No objective assessment of air pollutants levels was available at that time.

In this paper, we present for the first time results for HAI-AP in Bejaia city. Our HAI provided estimates of the number

of health events attributable to PM$_{10}$ in the target population. We proposed two scenarios: we first considered a scenario where the PM$_{10}$ annual mean is decreased by 5 $\mu$g/m$^3$ and then a scenario where the PM$_{10}$ annual mean is decreased to 20 $\mu$g/m$^3$ (WHO-AQ). To this extent, we conducted an ad hoc campaign to objectively assess PM$_{10}$ levels.

2. Methods

The HIA-AP method as previously described with relative risks from the dose-response functions as those used in the Aphekom City Report for the town of Marseilles [33] for short-term mortality and morbidity. The adverse health outcomes considered in this analysis include mortality (all causes except external causes, adults) and morbidity (respiratory and cardiac hospitalizations). RR = relative risk/10 $\mu$g/m$^3$ (Table 1) taken from Aphekom City Report Marseilles.

Two scenarios were considered (Table 2): the annual mean level of PM$_{10}$ is decreased by 5 $\mu$g/m$^3$, and PM$_{10}$ annual mean level is decreased to the WHO annual air quality guideline (20 $\mu$g/m$^3$).

2.1. Study Area. To satisfy the assumption of homogeneity in air quality, only urban areas were retained. There is a minimum geographical area compatible with the extraction of mortality data and hospital admissions which is the town of Bejaia, located 15 m above the sea (36° 45' 00" N and 5° 04' 00" E).

2.2. PM$_{10}$ Assessments. Due to lack of data on the quality of outdoor air in Bejaia, we chose to make by ourselves ad hoc outdoor pollution measurements. These measurements were performed for 4 months (04/08/2015 to 07/14/2015), this period coinciding with atmospheric stagnant conditions. In their study, Alkama et al. [34], studying seasonal variations of air pollution (CO, NO, and SO$_2$), showed that measured concentrations are strongly correlated with industrial activity and heavy traffic in this city: maximum values were observed in the summer period, while minimum values were measured in winter, a period in which wind speed produced high atmospheric dilution.

The underlying assumption is that air pollution during the given period was representative of the usual air pollution. PM$_{10}$ assessments were conducted in 8 stations in Bejaia city using a portable AEROCET 531S Particle Mass Profiler and Counter. Figure 1 presents the locations which were selected. PM measurements were carried out during the period. However, the analysis will focus on PM$_{10}$ because of the availability of PM$_{10}$ dose-response function in the literature. The AEROCET 531S is a full-featured, battery operated, handheld particle counter or mass monitor. The sample time is fixed at 60 seconds. The instrument store sample events. These records can be viewed on the display or transferred to a computer via USB or RS232. Data files were imported into an Excel® formatted output.

Before sampling, the AEROCET-531 monitor was tested with a zero filter and flow meters to ensure proper functioning of the monitor. During sampling, the instrument was placed at a height of 1.5 m from the soil and at a distance of 4 m from the road.

2.3. Health Data. Mortality data were obtained from both the Statistics Service of Directorate Planning and Regional Development (Direction de Planification et de l’Aménagement du Territoire: DPAT) and Directorate of Health and Population (DSP: Direction de la Santé Publique) of Bejaia. Table 2 describes population indicators and mortality rates for the period of analysis.

Data on hospitalization for cardiovascular and respiratory diseases were provided by the Pneumophtisiology Department at the Frantz Fanon Hospital.

Table 3 summarized collected health data.

3. Results

3.1. Air Quality. Figure 2 shows the distributions for PM$_{10}$. Most of the values fall around 81.7 µg/m$^3$, the mean of PM$_{10}$ except for a few outliers.

3.2. Health Data

3.2.1. Total Mortality. Among 1386 all-cause deaths in 2014 (Table 3), 4 deaths per year could be avoided according to the scenario of a reduction in annual PM$_{10}$ levels of 5 µg/m$^3$ and 55 deaths according to the scenario of a reduction in annual PM$_{10}$ levels to the WHO-AQG (20 µg/m$^3$) (Table 4).

3.2.2. Morbidity (Hospital Admissions). Decreasing PM$_{10}$ annual mean by 5 µg/m$^3$ would avoid 5.2 and 3.2 respiratory and cardiac hospital admissions, respectively (Table 4). If the annual average of PM$_{10}$ (87.8 µg/m$^3$) did not exceed the WHO-AQG (20 µg/m$^3$), there would be a decrease, or ΔX, of 67.8 µg/m$^3$. In this case the potential gain would be 36 per 100,000 and 23 per 100,000 for respiratory and cardiac hospital admissions, respectively (Figure 3).

4. Discussion

High levels of PM were observed in Bejaia, as over the sampling period the level average exceeded the WHO-AQG (20 µg/m$^3$) by 67.7 µg/m$^3$.

The specific Health Impact Assessment for Bejaia found that a significant health gain would be achieved by lowering annual means levels of PM$_{10}$. In particular, compliance with WHO-AQG for PM$_{10}$ (20 µg/m$^3$) would induce large benefits on mortality and cardiopulmonary hospital admissions. For the reduction scenario level of 5 µg/m$^3$, the number of avoidable deaths is 2 per 100,000 capita (0.3%) of the total mortality. This result is similar to that found in Marseilles. This town was taken in comparison because we used the same concentration-response function [13]. However for the second reduction scenario of compliance with WHO-AQG for PM$_{10}$ (20 µg/m$^3$), the result of 29 avoided deaths per 100,000 far exceeds the number of deaths found in Marseilles (5 deaths per 100000).

At the same time, we estimated that a reduction of 5 µg/m$^3$ in the existing PM$_{10}$ levels could diminish by about 3 per 100000 respiratory hospitalizations against 6 per 100000 in Marseilles and 36 per 100000 against 11 in the second scenario. Furthermore, according to the first scenario almost 2 (1.735) per 100000 cardiac hospitalizations could be avoided against 4 per 100000 in Marseilles. However, 23 per 100000 cardiac hospitalizations were avoided in the second scenario against 8 per 100000 in Marseilles.

From the public health point of view, our estimations clearly indicate that it is insufficient to reduce the PM$_{10}$ concentrations by 5 µg/m$^3$ in Bejaia and that it has to be reduced to the WHO-AQG.

Table 4: Annual number of health outcomes.
HIA with long-term effects will provide a better estimation of the strengths of reducing air pollution.

This is an approach by approximation. Our proxy is to take Marseille comparable to Bejaia, certainly more than any other European or American city with concentration-response function. However, we cannot discard the hypothesis of an underestimation of risk in our study in the absence of a local concentration-response function because the air quality in Bejaia is different from Marseilles.

Here we account only for PM$_{10}$ and HIA-AQ can be used to estimate HI with other pollutants. Depending on the availability of the measuring tools, there has been only 4 months of measurement. We thus plan to take a minimum of one year’s measurements. In future work we aim to include additional air quality data, for example, ozone and PAH, and focus more on fine PM and its components. We have to take more urbanistic typology and characteristics (not only car fleet characterization) for air pollution modelling in there.

This assessment on public health impacts of current patterns of PM$_{10}$ in Bejaia city is the first one. Our investigations into this area are in progress to confirm our hypothesis. We claim to do further analyses on pollution and health impacts not only on a minimum geographical area of Bejaia city but also on others areas.

5. Conclusion

We observed for the first time that, in the urban zones of Bejaia, annual average PM$_{10}$ levels exceeded the WHO limit of 20 µg/m$^3$, the EU limit of 40 µg/m$^3$, and the Algerian limits of 80 µg/m$^3$. These excess concentrations were responsible for 29 deaths, 36 respiratory hospitalizations, and 23 cardiac hospitalizations per 100,000 in 2014.

In conclusion, policies for the reduction of air pollution appear to be necessary, and their implementation will be rewarding in terms of the protection and improvement of individual and community health and installation of a monitoring and measuring site of air pollution is the basis of these policies.
