Abstract

Subduction infancy corresponds to the first few million years following subduction initiation, when slabs start their descent into the mantle. It coincides with the transient (yet systematic) transfer of material from the top of the slab to the upper plate, as witnessed by metamorphic soles welded beneath obducted ophiolites. Combining structure-lithology-pressure-temperature-time data from metamorphic soles with flow laws derived from experimental rock mechanics, this study highlights two main successive rheological switches across the subduction interface (mantle wedge vs. basalts, then mantle wedge vs. sediments; at $\sim 800^{\circ}\text{C}$ and $\sim 600^{\circ}\text{C}$, respectively), during which interplate mechanical coupling is maximized by the existence of transiently similar rheologies across the plate contact. We propose that these rheological switches hinder slab penetration and are responsible for slicing the top of the slab and welding crustal pieces (high- then low-temperature metamorphic soles) to the base of the mantle wedge during subduction infancy. This mechanism has implications for the rheological properties of the crust and mantle (and for transient episodes of accretion/exhumation of HP-LT rocks in mature subduction systems) and highlights the role of fluids in enabling subduction to overcome the early resistance to slab penetration.

51 **1. Introduction**

52

53 Understanding subduction initiation, in both space and time, has been a challenge since the
54 advent of plate tectonics (Dewey, 1976; Regenauer-Lieb et al., 2001; Gurnis et al., 2004). What is
55 referred to as "subduction initiation" in the literature encompasses two different concepts and
56 periods: (i) how and where subduction nucleates (i.e., what triggers the beginning of subduction;
57 e.g., Regenauer-Lieb et al., 2001; Stern, 2004), and (ii) how subduction proceeds over the first few
58 million years of its history ("subduction infancy"; Stern and Bloomer, 1992).

59 This study focuses on subduction infancy, when a newly born slab starts its descent into the
60 mantle and when the thermal regime of the subduction zone progressively cools down before
61 reaching steady-state (e.g., Syracuse et al., 2010; Plunder et al., 2015; Figs. 1a,b). The only rock
62 remnants of this elusive geodynamic step are thin (~10-500 m) metamorphosed slivers of oceanic
63 crust (metamorphic soles; Williams and Smyth, 1973; Wakabayashi and Dilek, 2000) found beneath
64 pristine, 100-1000 km long, ≤ 10 -15 km thick fragments of oceanic lithosphere emplaced on top of
65 continents as ophiolites (Coleman, 1981; Nicolas, 1989; Fig. 1c).

66 Metamorphic soles correspond to upper crustal material from the downgoing slab (with variable
67 proportions of basalts and pelagic sediments; Spray et al. 1984; Boudier et al., 1988) and have long
68 been recognized as formed during the first few My of intra-oceanic subduction (Fig. 1b; Dewey,
69 1976; Spray et al., 1984; Dewey and Casey, 2013). Their formation would result from heat transfer
70 from the upper plate mantle and/or shear heating when the slab enters the mantle and heats up
71 (Dewey, 1976; Hacker, 1990). Explaining how such thin metamorphosed tectonic slivers of oceanic
72 crust get welded ("underplated") to the upper plate along hundreds of km (e.g., Oman, Turkey:
73 Hacker and Gnos, 1997; Çelik et al., 2011) is essential for understanding mechanical coupling

74 during subduction infancy (and possibly during later subduction), but has so far remained enigmatic
75 (Jamieson, 1981; Dewey and Casey, 2013).

76 This problem is herein addressed by (i) compiling worldwide characteristics of metamorphic
77 soles (i.e., lithologies, internal organization, thicknesses, thermobarometric constraints), augmented
78 by refined estimates for their pressure-temperature (P-T) conditions of formation using
79 thermodynamic modelling and by (ii) calculating effective viscosities of materials present along the
80 plate interface from known rheological properties for the crust and mantle (i.e., peridotite, basalt,
81 sediment, serpentinite).

82 This study reveals the existence of rheological switches across the subduction interface, and
83 proposes that these changes in rheological properties control slab penetration into the mantle and
84 the formation of metamorphic soles during subduction infancy. This mechanism has implications
85 for effective rheologies of the crust and mantle and for the general understanding of accretion
86 processes and early slab dynamics.

87

88 **2. Metamorphic soles: the record of subduction infancy**

89

90 ***2.1 Metamorphic sole constitution***

91 The main characteristics (i.e., structural position, lithologies, constitution) and P-T conditions
92 of metamorphic soles worldwide are reviewed in figure 2 and Table 1. This synthesis shows that
93 metamorphic soles are ubiquitous beneath non-metamorphosed ophiolites (e.g., Oman, Turkey,
94 Papua, Newfoundland) and share similar characteristics regardless of the ophiolite or the detailed
95 geological/geodynamical setting (Spray, 1984; Wakabayashi and Dilek, 2003). Radiometric ages of
96 metamorphic soles and ophiolites generally fall within 1-2 My (e.g., Fig. 1d for Oman; Hacker et
97 al., 1996; Rioux et al., 2013), suggesting the existence of a still warm (i.e., > 1000°C) upper plate
98 mantle near the subduction interface.

99 Metamorphic soles comprise ~10 to ~500 m thick (Figs. 2b-c) highly strained and
100 metamorphosed crustal rocks where amphibolitized metabasalt dominates, together with increasing

101 proportions of pelagic metasediment structurally downwards (mainly metaradiolarite, with
102 intercalations of metatuff and metapelite downwards). Vertically, metamorphic soles exhibit an
103 inverted metamorphic sequence with isograds subparallel to the basal peridotite foliation (Spray,
104 1984). They grade steeply from thin high temperature (HT) granulite/amphibolite facies lithologies
105 adjacent to the overlying peridotites ($> 700\text{--}850^{\circ}\text{C}$; Fig. 2d; e.g., McCaig, 1983; Jamieson, 1986) to
106 thicker amphibolite/greenschist facies low temperature soles (LT; $\sim 550\text{--}650^{\circ}\text{C}$; Table 1). This
107 temperature trend is not continuous, however, since the structurally and thermally lower LT sole is
108 arguably formed later, and at lower pressure than the HT sole, by successive stacking of increasing
109 amounts of metasediment (e.g., Malpas, 1979; Casey and Dewey, 1984; Jamieson, 1986; Fig. 2d).
110 Whenever radiometric constraints are available, HT soles are coeval or slightly older than LT soles,
111 yet within ~ 2 My (e.g., for Oman: Fig. 1d; Hacker et al., 1996; Roberts et al., 2016). HT soles
112 and/or LT soles may be missing in places but wherever both are observed, and not disturbed by
113 obvious later tectonics, HT soles are overlying LT soles.

114 High deformation in the HT and LT soles is marked by mylonites and complex recumbent
115 folding. This deformation, however, is commonly less conspicuous in HT sole mafic amphibolites
116 than in the LT soles (Jamieson, 1981; this study), due to the extent of recrystallization (e.g., Oman)
117 and/or to the lack of lithological heterogeneities. Wherever (rarely) preserved, stretching lineations
118 in the HT soles and LT soles strike differently (e.g., Newfoundland; Dewey and Casey, 2013),
119 suggesting that boundary conditions and/or accretion dynamics may have been modified during
120 sequential underplating.

121 Some earlier workers, on the basis of rare gabbroic occurrences (associated with dunite and
122 locally intercalated between the mantle and the HT metamorphic amphibolite; Jamieson, 1981),
123 suggested that the whole metamorphic sole could represent a metamorphosed, overturned limb of
124 ophiolite crust (with sediments, basalts and gabbros from bottom to top; see also Wakabayashi and
125 Dilek, 2003). This interpretation is however unlikely: (i) in contrast with the ophiolite crust,
126 gabbros are extremely rare in the soles (and may represent small-scale intrusions in the mantle), (ii)
127 HT mafic amphibolites tend to have a distinctive nature/geochemical signature (i.e., MORB

transitional to OIB or E-MORB; Dewey and Casey, 2013) and (iii) the overturned limb hypothesis fails to explain why pressure conditions in the metasedimentary LT sole are lower than in the HT sole located above (Gnos, 1998; section 2.2).

The mantle rocks immediately above the metamorphic sole are also highly deformed (Fig. 2d), showing m- to hm-scale deformation patterns consistent with those observed in the underlying HT sole (Boudier et al., 1988), pressure estimates equivalent to those of HT sole peak metamorphism (Jamieson, 1981; McCaig, 1983) and porphyroclastic to ultramylonitic textures formed in the temperature range of 1100°C down to ~700°C (Boudier et al., 1988; Michibayashi and Mainprice, 2004; Linckens et al., 2011b). This suggests that the base of the ophiolite mantle deformed and cooled during subduction infancy and that, from a mechanical point of view, the metamorphic sole should be considered as a threefold stack with, from bottom to top, the LT sole, the HT sole and the base of the ophiolitic mantle sequence (hereafter noted as: LTsole\HTsole\basal peridotites).

2.2 *P-T conditions of metamorphic soles*

Published P-T estimates for metamorphic sole formation (Fig. 3a; Table 1) spread along a high to medium T/P gradient, which partly arises from the diversity and variable precision of thermobarometric methods used. New P-T estimates for HT soles are provided here using thermodynamic modelling. P-T phase diagrams for fixed bulk rock composition (pseudosections) were calculated to constrain the conditions of HT sole formation using the Gibbs-free-energy minimization software THERIAK/DOMINO (de Capitani and Petrakakis, 2010; with the updated database of Holland and Powell (1998); tcd55cc2d.bs) with the following solution models: Diener et al. (2007) for amphibole, Green et al. (2007) for clinopyroxene, White et al. (2007) for orthopyroxene, Holland et al. (1998) for chlorite, Baldwin et al. (2005) for plagioclase and Holland and Powell (1998) for garnet. P-T conditions for LT soles are difficult to assess, unfortunately, owing to the high variance of the assemblages and uncertainties in thermodynamic models.

A representative pseudosection (Fig. 3b) was calculated within the chemical system Na₂O–CaO–FeO–MnO–MgO–Al₂O₃–SiO₂–H₂O for a typical mafic amphibolite (YE1302b; Lycian

ophiolite, W. Turkey) with garnet, clinopyroxene, plagioclase and amphibole. The corresponding sample comes from the region of Salda (South Western Turkey; N037°46'44" E029°56'21"), where garnet-clinopyroxene amphibolites are passing downwards, away from the contact with the overlying peridotite, to amphibolites and then to greenschist facies rocks. Spinel is replaced by plagioclase in the nearby peridotite, suggesting former equilibration of the rock at pressures > 0.8-1 GPa. At the thin section scale, garnet and clinopyroxene are intimately intergrown (with globular shape inclusions of clinopyroxene in garnet). Amphibole and plagioclase are found both in the matrix and as inclusions in garnet and clinopyroxene, and therefore formed during peak conditions. Clinopyroxene has diopside compositions with Mg# ~ 0.80 and a Ca content of 0.88 - 0.91 per formula unit (p.f.u.). The pyrope content in garnet ranges between 0.20-0.28 p.f.u. and plagioclase (when preserved) has an anorthite fraction of 0.2-0.3.

P-T conditions for the garnet–clinopyroxene–amphibole–plagioclase peak assemblage of sample YE1302b, using mineral isopleths, are 1.08 ± 0.1 GPa and 780 ± 40 °C. Water amounts were set to match amphibole modes (50-60 vol%). TiO₂ was neglected in the calculation as it enters mainly accessory minerals (rutile, titanite) and amphibole, in which titanium is not accounted for (Diener et al., 2007). The MnO content reproduces the observed garnet chemistry and ensures consistent garnet and clinopyroxene Fe-Mg exchange.

A similar range of estimates was obtained with phase diagrams for metamorphic soles from Turkey (in Kütahya; boxes in Fig. 3a; Table 1) and Oman (in Sumeini and Khubakhib; dashed boxes, Fig. 3a), pointing to definitely high P values for the upper HT soles when compared to the spread of published estimates (i.e., black dots in Fig. 3a). This conclusion is strengthened by the similarity of available mineral assemblages and compositions worldwide. These estimates are consistent with the presence of only subordinate amounts of melts in the HT soles (Gnos, 1998), suggesting that temperatures do not significantly exceed amphibolite dehydration melting (in agreement with predicted melt fractions < 5-10 vol% at 850°C, depending on pressure; Green et al., 2016).

182

183 *2.3 Significance of metamorphic soles within thermal subduction regimes*

184 The above compilation shows that conditions for metamorphic sole formation are remarkably
185 similar worldwide and characterized by the accretion of HT soles that are thinner, more mafic,
186 accreted earlier, at greater depths, at almost invariant P-T conditions ($800 \pm 50^\circ\text{C}$ at 1.0 ± 0.2 GPa)
187 and always on top of LT soles (equilibrated at $\sim 600 \pm 50^\circ\text{C}$ at 0.5 ± 0.1 GPa).

188 These estimates are compared to peak conditions reached by oceanic rocks during later
189 subduction, namely those for HT and LT eclogites (Fig. 3a; see Agard et al., 2009 for a review).
190 Their contrasting P-T conditions exemplify the change in the subduction thermal gradient through
191 time, from warm to cold, from peak burial conditions of $\sim 800^\circ\text{C}$ and 1.0 GPa to $\sim 550^\circ\text{C}$ and 2.5
192 GPa. Figure 3a shows that during subduction infancy and subsequent cooling, three rock types
193 successively form from the upper crust of the down-going slab: (1) metamorphic soles within the
194 first 1-2 My, along the hotter gradient, (2) HT oceanic eclogites postdating initiation by ~ 5 My,
195 commonly exhumed in serpentinite mélanges with counter-clockwise P-T paths (arrows in Fig. 3a;
196 e.g., Wakabayashi, 1990; Garcia-Casco et al., 2006), (3) LT oceanic eclogites formed after 5-10 My
197 and, whenever exhumed, mostly as continuous tectonic slices.

198 Contrary to metamorphic soles, the fraction of eclogites exhumed worldwide is only rarely
199 accreted to an upper plate ophiolite mantle. Figure 3a also shows that accretion largely overlaps the
200 domain where serpentine is not stable.

201 Most HT metamorphic soles do not show later HP-LT metamorphism overprint, such as would
202 be expected from progressive cooling if these rocks had remained at their depth of formation. The
203 implication is that the HT soles formed at ~ 1 GPa must have been accreted and partly exhumed
204 (together with the deformed base of the ophiolite mantle) during subduction infancy (i.e., before
205 significant cooling of the subduction thermal regime), and later underplated below the undeformed
206 ophiolite mantle.

207

208

3. Rheology of the plate interface and mechanical coupling during subduction infancy

A generic mechanical process is needed to explain how slices of crustal material from the slab get accreted to the mantle wedge (i) only during subduction infancy and (ii) in such a uniform manner. Accretion (or "underplating") of any tectonic slice across the subduction interface requires the combination of:

(i) an increase in mechanical coupling across the plate contact beyond some threshold, in order to preferentially localize strain and relative displacement elsewhere within the slab, along some other physical discontinuity (e.g., basalt vs. sediment, or basalt vs. sheeted dykes; Kimura and Ludden, 1995; Dewey and Casey, 2013),

(ii) some deformation mechanisms allowing for effective slicing within the slab. Whether slicing takes place through slow creep, fluid-mediated slip (such as slow slip events) or repeated regular earthquakes is unknown to date and beyond the scope of the present study.

Noteworthy, mechanical coupling is maximum when rheologies on both sides of the plate interface are similar: strain is otherwise localized and the interface is decoupled.

3.1 Effective viscosities of plate interface material constrained by rock mechanics

Flow laws derived from experimental rock mechanics (Table 2) are used to estimate the effective viscosity (η) of plate interface materials as a function of temperature (T). Figure 4a shows this dependency for rocks expected to lie at the base of the upper plate (peridotite, serpentinite) and at the top of the slab (basalt, sediment), using a strain rate ($\dot{\epsilon}$) derived from natural constraints (10^{13} s^{-1} for Oman; Linckens et al., 2011b) and the following formula:

$$\eta = \frac{1}{2} A^{-\frac{1}{n}} \dot{\epsilon}^{\frac{1-n}{n}} \exp\left(\frac{Q}{nRT}\right)$$

where n , A , Q and R correspond to the power-law exponent, the material constant, the activation energy and the gas constant, respectively.

The reader is referred to Karato (2010) and Hirth and Kohlstedt (2015) for reviews of flow laws of relevance for the mantle. These were derived from experiments on dry or wet olivine for

236 dislocation creep (e.g., Hirth and Kohlstedt, 2003) and for grain size dependent deformation
237 mechanisms such as diffusion creep (Hirth and Kohlstedt, 2003; Faul and Jackson, 2007) and
238 dislocation-accommodated grain boundary sliding (disGBS; Hirth and Kohlstedt, 2003; Hansen et
239 al., 2011). Important independent constraints on mantle deformation along the plate interface come
240 from natural data on basal peridotites and mantle shear zones rooting in the deformed mantle base
241 of the ophiolite (Boudier et al., 1988; Linckens et al., 2011a,b). The evolution from 1100°C in
242 porphyroclastic peridotites to ~700°C in ultramylonites shows that (i) olivine grain size decreases
243 from ~2 mm to 10-50 μm and (ii) deformation mechanisms evolve at ~800-850°C from dislocation
244 creep to grain size sensitive creep, diffusion creep being the most likely dominant mechanism in
245 localized shear bands (the boundary between diffusion creep and disGBS is not well known
246 however; Linckens et al., 2011b).

247 Flow laws for metamorphic sole mafic rocks are scarce in comparison and can be approached
248 by using wet/dry diabase and mafic granulite. Flow laws are even scarcer for metasediments (Table
249 2). Given the abundance of metaradiolarites in the LT soles, the flow law of quartz is considered
250 here as representative. Felsic granulite (dashed purple curve; Fig. 4a) may represent an equivalent to
251 a strongly metamorphosed metasediment.

252 Importantly, at any given temperature and (at least as a first order approximation) regardless of
253 which flow law is used, the mechanical strength of peridotite (i.e., dry or wet olivine: thick green
254 curves and green overlay, respectively; Fig. 4a) is greater than that of mafic oceanic crust (blue
255 overlay in Fig. 4b). Sediments are weaker than basalt, yet stronger than serpentinite. This is
256 emphasized in figure 4b, where averages of flow laws are shown for the mantle (i.e., dislocation
257 creep for dry and wet olivine and diffusion creep or disGBS with a grain size of 30 μm), for the
258 mafic crust ("basalt") and for serpentinite. It is emphasized that changing the strain rate modifies the
259 absolute value of η but does not affect the relative position of these curves (see supplementary
260 figure S1). The strength contrasts existing between these different materials therefore seem
261 independent of strain rate.

262

3.2 Rheological switches across the plate interface

Slab dehydration (see Faccenda, 2014 for a review) can be anticipated to be critical for mechanical coupling during subduction infancy. Fluids released into the nascent mantle wedge (Fig. 4c) will induce serpentinization of the mantle below ~550-650°C (depending on pressure: Fig. 3a; Ulmer and Trommsdorff, 1995). These fluids will be stored in progressively lesser amounts deeper down, first as hydrous phases such as chlorite $\pm$ amphibole $\pm$ phlogopite $\pm$ talc, then at $T > \sim 850$ -900°C as fluid inclusions or point defects in nominally anhydrous minerals such as olivine or pyroxene (Hirth and Kohlstedt, 2015).

Contrary to the general increase of material strength with cooling (Fig. 4b), cooling of hydrated mantle wedge peridotites will therefore progressively weaken the mantle wedge towards serpentinite rheology (from point i to f; Fig. 4b) by (i) absorption of OH in olivine ("wet" olivine) at 1000-900°C and changes in deformation mechanisms from dislocation creep to grain size sensitive creep at $T < \sim 850$ -900°C (i.e., diffusion creep and disGBS), (ii) formation of weaker hydrated minerals and eventually (iii) serpentinization. Noteworthy, the viscosity of an even mildly serpentinised peridotite ($> 15\%$) approaches that of pure serpentine (Escartin et al., 2001).

Although the exact rheological path from peridotite to serpentinite cannot be precisely quantified presently, an important conclusion is that mantle wedge viscosities will cross over the curves for metabasalt and then metasediment (Fig. 4b): these two "rheological switches" (i.e., when the mantle wedge first becomes weaker than basalts, then than sediments) most probably occur at $T \sim 800$ °C (where deformation by diffusion creep and disGBS have similar effective viscosities; Figs. 4a,b) and ~ 600 °C, respectively. The temperature and viscosity values for the HT rheological switch (Fig. 4d) both match the temperature ($T \sim 800$ -850°C; Boudier et al., 1988; Linckens et al., 2011a) and viscosity ($\eta \sim 10^{20-21}$ Pa.s; Linckens et al., 2011b; Tasaka et al., 2014) inferred from the high strain mylonitic to ultramylonitic deformation of adjacent banded peridotites from the base of the ophiolite.

4. Model for slab penetration into the mantle and metamorphic sole formation

4.1 Evolution of rheological contrasts across the plate interface during subduction infancy

Figure 4d shows the evolution of the rheological contrast across the plate interface during incipient slab penetration, as the top of the slab progressively heats up, weakens and dehydrates. The top of the slab is first considered as essentially made of mafic crust (i.e., basalt; Fig. 4c), sediments being probably scarce at the start of intra-oceanic subduction, far away from the continent (Fig. 1a). At shallow depths and for temperatures below ~550-600°C, the subducting oceanic (basaltic) crust is juxtaposed against an incipiently serpentinised mantle on top (as schematized in Fig. 4c). A sharp viscosity contrast ($\Delta\eta$) exists on either side of the subduction plane (strong basalt vs. weak mantle wedge; Fig. 4d).

As depth and temperature increase, the subducting crust weakens and progressively encounters a warmer, stronger, un-serpentinised and less hydrated mantle wedge ($\Delta\eta'$ on Fig. 4d), where grain size sensitive deformation mechanisms take over (Linckens et al., 2011a; Hirth and Kohlstedt, 2015). The viscosity contrast across the interface reverses (weak basalt vs. stronger mantle wedge) at $T > \sim 800^\circ\text{C}$, once the subducting crust is juxtaposed against an almost dry peridotite rheology ($\Delta\eta''$ on Fig. 4d).

A similar evolution can be envisioned if sediments are present on top of the slab, with a viscosity reversal (sediment vs. mantle wedge) taking place at $\sim 600^\circ\text{C}$ ("second rheological switch"; Fig. 4d). Although the extent to which basalts and sediments harden as a result of prograde mineral transformations is unknown, flow laws indicate that these rheological switches exist, even considering the change from basalt to mafic granulite or from sediment/quartzite to felsic granulite (Fig. 4a). They will also take place regardless of the age of the overriding lithosphere, although at different depths (the warmer the lithosphere, the shallower the rheological switches).

Rheological switches bear major consequences on mechanical coupling during early slab penetration:

316 (i) at any given time the strength of the mantle wedge will increase downwards (Fig. 4c), so
317 that the slab can be expected to face greater resistance to penetration with depth (at least until
318 mantle melting occurs);

319 (ii) as the thermal regime cools with time, the domain where serpentine is stable ("serp. front"
320 in Fig. 4c) will expand continuously downwards.

321

322 ***4.2 Metamorphic sole formation linked to strong interplate mechanical coupling***

323 Effective viscosities of the lower plate crust and upper plate mantle therefore converge and
324 switch, during subduction infancy, across restricted T windows (Fig. 4d; with P and time generally
325 ~ 1 GPa and < 2Myr, these are restricted P-T-t windows too). We propose that the detachment and
326 accretion of metamorphic soles is triggered by peaks of interplate mechanical coupling associated
327 with rheological switches, that distribute deformation over large, km-scale bands across the
328 subduction interface (e.g., Yuen et al., 1978) and localize strain further into the slab where/if a
329 sharper viscosity contrast exists (e.g., Kimura and Ludden, 1995).

330 Slab penetration and metamorphic sole formation are tentatively reconstructed in figure 5 in
331 three major steps (isotherms and depth-time trajectories are from thermo-kinematic models detailed
332 in supplementary material; Figs. S2-4):

333 (1) Plate interface mechanical strength peaks during the first rheological switch
334 (metamorphosed basalt vs. metasomatized upper mantle; Fig. 5a) at T~750-850°C, leading to the
335 formation of essentially mafic HT metamorphic soles (dot 1a, Fig. 4d). Detachment on a weaker
336 horizon within the slab probably takes place at the transition between hydrothermalized/weakened
337 basaltic layers and drier basalts below, and/or between basalts and sheeted dykes (if present),
338 accounting for the general lack of metagabbros in metamorphic soles.

339 (2) Accretion of the metasedimentary-rich LT soles takes place at lower T (and P) conditions at
340 ~550-650°C and ~0.5 GPa, after the partial exhumation of the HT sole (Fig. 5b). This corresponds
341 to the second rheological switch (dot 1b, Fig. 4d). Two different scenarios of mechanical coupling
342 can however be envisioned: (i) between the sediments and the incipiently serpentinised, weakening

upper mantle (option 1; Fig. 5d) or (ii) between the sediments and the base of the HT sole (option 2; Fig. 5d), whose viscosity will be shifted from basalt to sediment as the sedimentary column increases (blue arrow, Fig. 4b; a similar shift is expected if strain rate increases or if basalt from the HT sole get hydrated by water released from sediments below). Option 2 is supported by the general lack of (serpentinised) mantle between the LT and HT sole (see section 2). Option 1 implies that the mantle above the LT sole is tectonically removed by the exhumation of the (more resistant) HT sole and basal peridotites (Fig. 5d). Option 1 would nevertheless explain the occurrence of LT soles directly beneath the mantle. Accretion of the LT sole indicates, in any case, that the detachment horizon within the slab is located within the sedimentary pile.

The fact that HT soles are thinner than LT soles could result from larger amounts of accumulated strain and later ductile thinning, from the peeling of thinner slices during the first rheological switch and/or from longer duration of accretion during the LT episode.

(3) As the thermal regime of the subduction continues to decrease (Fig. 5c), incoming sediment and basalt remain stronger than the increasingly serpentinised mantle wedge (Fig. 4d): the plate interface progressively 'unzips' downwards. LT eclogites, which start forming within the refrigerated subduction zone (Fig. 5c), are less likely to get mechanically coupled to the weakened upper plate. This can be the reason why they are rarely exhumed (Agard et al., 2009), in agreement with their location in the serpentine stability field ("no accretion" domain in figure 3a).

361

362 ***4.3 Impact of subduction cooling on interplate mechanical coupling***

Figure 5 highlights how cooling dramatically impacts slab penetration during subduction infancy:

(i) The mantle wedge acts as a buttress which progressively softens with time: it only transiently peels off the slab crust during the first My, thereby forming metamorphic soles, then progressively loses strength with cooling/serpentinization until full decoupling;

(ii) Strain localizes with time in shallower decoupling horizons within the slab (Fig. 5e): accretion affects the top of the mafic crust (stage a), then only the sediments on top (stage b) and, when the

370 plate interface becomes decoupled after a few My (stage c), accretion is restricted to shallow, near-
371 trench infill (e.g., unmetamorphosed Hawasina units found in Oman beneath the metamorphic sole
372 and the ophiolite; Searle and Malpas, 1980; Searle and Cox, 2002), as in present-day accretionary
373 wedges (e.g., Nankai prism). The width of the plate interface shear zone may therefore decrease
374 with time.

375

376 **5. Discussion**

377

378 The proposed mechanism for metamorphic sole formation and slab penetration (Fig. 5)
379 explains why, through two main steps of accretion, metamorphic soles form and get accreted at
380 remarkably similar P-T-time conditions worldwide (section 2.3) and across a transient period of
381 subduction lifetime only (i.e., when rheological switches take place).

382

383 ***5.1 Uncertainties on P-T-time conditions, viscosity estimates and strain rate***

384 ***5.1.1 P-T-time constraints***

385 P-T estimates ($800 \pm 50^\circ\text{C}$ at 1.0 ± 0.1 GPa for the early thin HT sole and $600 \pm 50^\circ\text{C}$ at $\sim 0.5 \pm$
386 0.1 GPa for the late, thicker LT sole; Fig. 3) depend on the accuracy of thermodynamic models for
387 pyroxene and amphibole. These models were considerably refined but Ti- and Fe^{3+} - substitutions in
388 amphiboles are complex and mafic melts are notoriously difficult to model (Diener and Powell,
389 2012 and references therein; Green et al., 2016). Larger uncertainties on pressure conditions for LT
390 soles arise from lesser constraints in the high-variance greenschist to epidote amphibolite fields.
391 The major uncertainty therefore lies in the exact pressure gap between the HT and LT soles, and
392 whether there might be a continuum in between.

393 Age constraints for HT and LT metamorphic soles tightly cluster within 1-2 My (Table 1; Fig.
394 1d). The short duration of the process and/or apparent synchronicity might be exaggerated by the
395 fact that $^{40}\text{Ar}/^{39}\text{Ar}$ ages on amphibole may represent cooling ages for the HT soles (i.e., below
396 550°C), whereas age constraints for the LT sole could represent crystallization ages. But the fact

397 that the LT soles are found below the HT ones (whom underlie the mantle base of the ophiolite)
398 leaves little doubt that they were accreted afterwards. Thermo-mechanical modelling of a cooling
399 subduction zone also shows that cooling lasts no more than a few My (Duretz et al., 2015).

400

401 *5.1.2 Viscosities and strain rates*

402 One of the largest uncertainties with experimental flow laws is that they are performed at (and
403 extrapolated from) conditions orders of magnitude faster than nature (typically 10^{-4} - 10^{-6} s⁻¹ versus
404 10^{-12} - 10^{-15} s⁻¹ in nature; Burov, 2011; Hirth and Kohlstedt, 2015). Field evidence, however, suggests
405 that mafic, clinopyroxene and plagioclase bearing lithologies are ~2 orders of magnitude weaker
406 than dry peridotite at ~700-800°C (e.g., Homburg et al., 2010), in agreement with the respective
407 position of calculated flow laws (Fig. 4b,c). Viscosity estimates for the first, HT rheological switch
408 ($\sim 10^{20-21}$ Pa.s; Fig. 4d) are also in remarkable agreement with values deduced from natural
409 observations on strained peridotites from the (ultra)mylonitic base of the ophiolite mantle (10^{20-21}
410 Pa.s; Linckens et al., 2011b; Tasaka et al., 2014).

411 Another uncertainty comes from the simplifying assumption of considering similar strain rates
412 for estimating the viscosities of all lithologies (Fig. 4b), whereas faster strain rates can be expected
413 where strain localization takes place. Regardless of strain rate, however, "rheological switches" and
414 converging mechanical behaviour between the mantle and basalt/sediment will take place across the
415 interface: as the mantle wedge evolves progressively from dry to serpentinised, its viscosity curve is
416 bound to cross that of basalt then of sediment (Fig. 4b,d), and this order is independent of strain rate
417 (e.g., from 10^{12} to 10^{14} s⁻¹; Fig. S1). This conclusion is not modified by shear heating either, which
418 only changes the temperature field and shifts the T window of metamorphic sole formation to
419 shallower depths, but not the characteristic "S-shape" of the isotherms (Fig. S5; so does the thermal
420 state of the upper plate: Figs. S2b,c).

421 Complex feedbacks may nevertheless exist, since similar viscosities on each side will increase
422 interplate mechanical coupling, which will in turn decrease strain rates, hence probably decrease
423 shear heating (also depending on the width onto which deformation is distributed). Further testing

424 of this scenario using self-consistent fully coupled thermomechanical models is therefore needed,
425 but there are major challenges:

426 (i) refined rheologies for sediments, variably hydrated basalts and gabbros, taking into account
427 the influence of hydrothermal alteration, progressive metamorphic recrystallization, water loss or
428 plagioclase content on crustal rocks are unknown (e.g., Getsinger and Hirth, 2014). The same holds
429 true for the rheology of the mantle wedge (as yet unconstrained, as is fluid migration inside;
430 Faccenda, 2014), for polyphase lithologies that also probably exist along the plate interface, for the
431 impact of subordinate amounts of melt in the HT soles ($< \sim 10\%$), or for assessing the influence of
432 pressure or the extent to which frictional energy is converted into heat (which also depends on
433 rheological laws).

434 (ii) appropriate spatial resolution (i.e., down to ~ 10 m) is required in self-consistent visco-
435 elasto-plastic geodynamic models in order to localize strain and (progressively) slice and detach
436 pieces from the slab, in addition to reaching sufficient temporal resolution (e.g., van Dinther et al.,
437 2014).

438 Further modelling will help constrain the depth and duration of these processes. The simple
439 thermo-kinematic models used to derive the isotherms of figure 5 (see supplementary material)
440 suggest that for a set of realistic velocities, initial thermal age and slab dip, incoming crustal rocks
441 may cross the temperature range of HT sole formation (~ 750 - 850°C) at depths of ~ 25 - 35 km and
442 that accretion of individual slices may last on the order of 0.3 - 0.4 My (Fig. S3). Although inferred
443 from simplified models, these constraints point to the possible formation of metamorphic soles
444 across a range of depths, possibly accounting for some of the scatter observed in the P-T estimates
445 for metamorphic soles worldwide (Fig. 3a).

446

447 ***5.2 Accretion and exhumation during subduction infancy***

448 ***5.2.1 Accretion of HT soles and incorporation of HT eclogites in serpentinite mélanges***

449 Accretion of mafic HT soles will last less than shown in the reconstruction and probably stop
450 (or decrease) once a significant amount of sediments reaches the trench and becomes involved in

451 the plate interface (Fig. 5b): since incoming sediments reach their rheological switch with the
452 mantle wedge at lower T than basalts (Figs. 4c,d), their arrival along the plate interface will indeed
453 localize strain and thus deactivate basalt accretion.

454 As a result of progressive cooling of the subduction zone, potential accretion of HT soles
455 further downdip can be predicted for a few more My after subduction initiation (Fig. 5b). Such
456 rocks, however, are not accreted below ophiolites and/or not exhumed, which could be due to rock
457 densities exceeding mantle values (thermodynamic modelling shows that this will be the case for
458 basalt at 800°C for $P > 1.2$ GPa), to dynamics associated with melting at depth (Faccenda, 2014)
459 and/or to the resumption of full coupling between the plates (Syracuse et al., 2010) dragging down
460 these rocks irreversibly.

461 In contrast, later and further downdip, the mantle wedge will get colder, more hydrated and
462 therefore more buoyant while transiently remaining fairly strong (i.e., still mechanically strongly
463 coupled). HT eclogites and the heterogeneously hydrated/weakened mantle wedge may thus reach
464 broadly equivalent viscosities towards the end of subduction infancy, thereby favouring mechanical
465 coupling, rock mixing and fast (buoyant) joint exhumation. This could explain the anticlockwise,
466 short-lived exhumation of HT eclogites in serpentinite mélanges at depths of 50-60 km and ~5 My
467 after subduction nucleation (Figs. 3a, 5c; e.g., Franciscan complex or Serpentinite mélange of Cuba:
468 Garcia-Casco et al., 2006).

469

470 *5.2.2 Exhumation of HT soles and basal peridotites: the depth conundrum*

471 This study highlights the contrast between the juxtaposition of HT soles and basal peridotites at
472 ~25-35 km (assuming purely lithostatic P estimates) and the final ophiolite thickness (≤ 10 -15 km).
473 Whether this can be explained by mantle thinning (Casey and Dewey, 1984; Dewey and Casey,
474 2013) or relative exhumation (or both) has been a matter of speculation (e.g., the "conundrum of
475 Samail"; Hacker and Gnos, 1997). Mantle thinning would have to be concentrated within the basal
476 peridotites (500-1000 m thick at present) as the rest of the mantle section is mostly undeformed

477 (Ceuleneer et al., 1988; Nicolas et al., 2000), and does not explain how metamorphic soles get
478 accreted.

479 Based on the pressure difference between the HT and LT soles and on the similar P-T
480 conditions retrieved from HT soles and basal peridotites (e.g., Jamieson, 1981; McCaig, 1983; this
481 study), the reconstruction of figure 5 depicts their relative exhumation with respect to the rest of the
482 overlying oceanic lithosphere, thanks to buoyancy/rheology contrasts (and through successive
483 stacks: HTsole\peridotite, then LTsole\HTsole\peridotite). The lower density of the slices would
484 account for their exhumation with respect to the overlying mantle, while the rheology (viscosity)
485 constrasts above and below the slices would favour strain localization. Relative exhumation is also
486 supported by the existence of rare blueschist facies overprints on HT soles underlain by blueschist
487 facies rocks (e.g., Turkey; Plunder et al., 2015, 2016), indicating that, in some cases, the HT sole is
488 not immediately exhumed and stagnates at depth (which would not be the case if the mantle was
489 systematically thinned).

490 An alternative explanation to the depth conundrum could be that the ~1 GPa pressure estimate
491 for the HT soles corresponds to overpressure arising from strongly coupled lithologies (i.e., dry
492 mantle against basalt; McCaig, 1983). Depths attributed to the deformation of HT soles and basal
493 peridotites could then be reduced by up to a factor of 2 (Petrini and Podladchikov, 2000), matching
494 both the depths/pressures of LT soles and final ophiolite thickness (~10-15 km). Whether such
495 rocks, affected by strong ductile deformation, may sustain excess dynamic pressure is unclear and
496 could be tested with numerical models (with limitations discussed in section 5.1.2). Overpressure
497 would not, however, affect the conclusions of this study regarding mechanical coupling, accretion
498 or the existence of rheological switches.

499

500 *5.2.3 Are metamorphic soles formed beneath supra-subduction ophiolites?*

501 While the proposed mechanism emphasizes the importance of rheology during subduction
502 infancy, the nature and genesis of ophiolites is still a matter of debate (see Rioux et al., 2013 for a
503 recent discussion), with authors in favour of a MORB-type pre-existing lithosphere (Nicolas, 1989;

504 Nicolas et al., 2000) and others supporting an entirely supra-subduction origin (Stern and Bloomer,
505 1992). In the first hypothesis, formation of oceanic lithosphere shortly predates intra-oceanic
506 subduction (via near-ridge, detachment or transform fault inversion; Boudier et al., 1988), while in
507 the second hypothesis intra-oceanic spontaneous subduction (often assumed to take place at
508 transform faults) triggers the formation of supra-subduction lithosphere by mantle upwelling (e.g.,
509 Stern and Bloomer, 1992). The interplay between lithology/rheology, T (and P) and mechanical
510 coupling of our proposed mechanism could in principle operate through either inversion of small
511 oceanic basins or mantle upwelling following spontaneous subduction initiation. The second
512 scenario, however, less easily explains the systematic juxtaposition of HT soles onto LT soles (and
513 the sharp lithological divide between them), as well as the slightly younger and more dispersed ages
514 of the metamorphic soles when compared to those of the ophiolite crust (Fig. 1d; Wakabayashi and
515 Dilek, 2000, 2003). Metamorphic sole formation may thus question the popular spontaneous
516 subduction initiation model (Stern and Bloomer, 1992).

517

518 ***5.3 Rheological implications***

519 An important inference from this model is that the effective rheologies of the mantle and crust
520 are similar at ~800°C and ~1 GPa in the presence of fluids. This is an important anchor point for
521 experimental rock mechanics, supporting the validity of extrapolations from laboratory experiments
522 performed orders of magnitude faster than in nature. Although the viscosity-temperature path of the
523 mantle wedge (from i to f; Fig. 4b) or location of the first rheological switch are not determined
524 with precision yet, their location (at $\pm 50^\circ\text{C}$ and ~1 order of magnitude in viscosity) further supports
525 the convergence of the experimental grain size dependent flow laws at ~800°C (i.e., at the
526 temperature of HT sole formation; Fig. 4d).

527 Figure 5 also highlights the importance, for strain localization during subduction infancy, of
528 lubrication by hydrous phases (Regenauer-Lieb et al., 2001; Dymkova and Gerya, 2013) and grain
529 size reduction (Linckens et al., 2011b; Hirth and Kohlstedt, 2015). Viscosity estimates for sole
530 formation (Fig. 4d) match those inferred for the nucleation of throughgoing low viscosity shear

531 zones ($\sim 10^{20}$ Pa.s; Regenauer-Lieb et al., 2001). Although mantle wedge rheology likely depends on
532 the extent of serpentinization and higher T ductile deformation, the similarity of ophiolite soles
533 worldwide suggests that regional variations (e.g., incoming material, convergence rates, effective
534 fluid release) are averaged out.

535 The presence of a warm oceanic lithosphere (i.e., $< \sim 3$ My and/or rejuvenated; Hacker, 1990;
536 Duretz et al., 2015; supplementary material) appears to be an important requirement for
537 metamorphic sole formation. Their formation is probably inhibited for older lithospheres, not
538 because they are too cold (warm conditions will be met deeper down) but because the plate
539 interface will be too decoupled. On the other hand, previous studies suggested that one-sided
540 intraoceanic subduction initiation requires significant mantle cooling and subsequent weakening
541 (Crameri et al., 2012). Too strong mechanical coupling, during subduction infancy, would favour
542 double-sided subduction as in the Archean (Sizova et al., 2010 and references therein). This
543 potentially explains why ophiolite soles older than the Neo-proterozoic are missing.

544 These findings also bear important implications for mechanisms of sediment or seamount
545 underplating (i.e., transient episodes of strong coupling may control, in long-lived subduction
546 systems, the potential accretion/exhumation of HP-LT rocks, including eclogites; Kimura and
547 Ludden, 1995; Agard et al., 2007), variably hydrated mantle wedge rheologies (Faccenda, 2014)
548 and for geochemical budgets of volatile fluxing during (hot) subduction (Ishikawa et al., 2005;
549 Sizova et al., 2010).

550

551

552 **6. Conclusions**

553

554 Combining structure-lithology-P-T-time data from metamorphic soles with flow laws derived
555 from experimental rock mechanics, we herein (i) outline the existence of two major, systematic
556 rheological switches across the subduction interface (mantle wedge vs. basalts, then mantle wedge
557 vs. sediments), (ii) propose that they control slab penetration and the successive formation of HT

558 then LT metamorphic soles and (iii) provide a tentative reconstruction of metamorphic sole
559 accretion during subduction infancy.

560 This reconstruction provides a generic explanation for the ubiquitous formation of
561 metamorphic soles and emphasizes how slab progression is hindered, during subduction infancy, by
562 progressive changes in the mechanical properties of the cooling plate interface, until the interface
563 becomes fully decoupled. Metamorphic sole formation and accretion would not so much result from
564 a transient HT event (i.e., an 'ironing' effect), but from the existence of transiently similar rheologies
565 and strong coupling during subduction infancy.

566 This study sheds light on early slab dynamics and on the role of transient mechanical coupling
567 along the plate interface (i.e., such transient episodes may also control accretion/exhumation of HP-
568 LT rocks in mature subduction systems) and provides a testable hypothesis for thermo-mechanical
569 models. The proposed mechanism also strengthens the applicability of experimentally-derived flow
570 laws for the mantle and mafic crust: although calibrated at much higher strain rates, they appear to
571 be in remarkable agreement with natural data at ~800°C (and ~1 GPa).

572

Fig. 1

Figure 1

(a) Geodynamic setting of metamorphic sole formation during subduction infancy, following intra-oceanic subduction initiation. The later geodynamic evolution will lead to continental subduction and obduction s.s. (i.e., emplacement of the oceanic lithosphere onto continental lithosphere; after Agard et al., 2007); (b) Close-up view of Fig. 1a: the formation and accretion of metamorphic soles imply a shift of the subduction interface during subduction initiation (from thrust 1 to thrust 2); (c) simplified geological map highlighting the striking continuity of the metamorphic sole beneath the mantle of the Oman ophiolite (modified after Nicolas et al., 2000); (d) age constraints for metamorphic sole formation along the Oman ophiolite (Hb: hornblende; Ms: white mica; Zr: zircon; see Table 1 for references). Radiometric ages for the ophiolite are shown for comparison (after Rioux et al., 2013; see discussion in section 5.2).

Figure 2

(a) Location of metamorphic soles and of the main large-scale obducted ophiolites worldwide (spanning late Proterozoic to Phanerozoic times); (b) and (c): histograms of thicknesses for metamorphic soles (after Table 1); (d) general structure of ophiolite soles (not to scale), emphasizing differences between the HT and LT sections. (temperature indications after Fig. 3a). Note the strongly deformed mantle section at the base of the ophiolite. Thrusts 1 and 2 as in figure 1b.

Figure 3

(a) Compilation of pressure-temperature data for HT (black) and LT (white) metamorphic soles (see Table 1; all are enclosed in the grey shaded area). P-T conditions for representative eclogites (HT: purple; LT: white) are also given for comparison (after Agard et al., 2009). Arrows outline counterclockwise P-T paths for HT eclogites. Boxes in the HT sole domain correspond to phase diagram calculations in this study. Plain boxes: results for two sample locations in Turkey (Kütahya and Yesilova); dashed boxes: results for two locations in Oman (Sumeini and Khubakhib). The diamond-shaped box with a thicker contour corresponds to the estimate for the HT sole sample from Yesilova described in the text and in figure 3b. Samples have the following molar proportions (%): Kutahya: Si (46.92), Al (16.14), Fe (9.98), Mg (10.08), Ca (10.49), Na (6.39) / Yesilova: Si (44.29), Al (16.77), Fe (7.68), Mn (0.45), Mg (15.52), Ca (10.37), Na (4.14) / Sumeini: Si(43.24) Al(15.66) Fe(10.46) Mg(11.37) Ca(16.81) Na(2.46) / Khubakhib: Si(44.85) Al (15.67) Fe(8.82) Mg(11.51) Ca (14.36) Na (4.79). (b) Phase diagram calculated in the Na₂O–CaO–MnO–FeO–MgO–Al₂O₃–SiO₂–H₂O chemical system for a MORB-type HT metamorphic sole (YE1302b; Lycian ophiolite, W. Turkey). The studied equilibrium peak assemblage (i.e. garnet–clinopyroxene–amphibole–plagioclase) is stable within a P-T field refined using mineral isopleths (e.g., pyrope content in garnet: X_{Prp} ; Calcic component in clinopyroxene: Ca_{Cpx}) to 1.08 ± 0.1 GPa and 780 ± 40 °C. Abbreviations for minerals with solid solutions: Amph: amphibole; Cpx: clinopyroxene; Ep: epidote; Grt: garnet; Opx: orthopyroxene; Plg: plagioclase; Qtz: quartz.

Fig. 4

Figure 4

(a) Calculated temperature dependency of effective viscosities (η) for key plate interface lithologies (peridotite, basalt, sediments and serpentine; see Table 2 and section 3.1 for details) for an average strain rate of 10^{-13} s^{-1} (after the Oman example; Linckens et al., 2011b). Note the systematic location of the dry and wet olivine dislocation creep flow laws above those for mafic rocks (i.e., basalt, blue overlay). Abbreviations: disGBS: dislocation-accommodated grain boundary sliding; diff creep: diffusion creep; FJ07: Faul and Jackson, 2007; HK03: Hirth and Kohlstedt, 2003. Diffusion creep flow laws have been calculated for two different olivine aggregate grain sizes (10 and 50 μm) corresponding to the extreme values estimated by Linckens et al. (2011b) in Oman mantle ultramylonites.

(b) Plot of averages of published flow laws (after Fig. 4a) showing the qualitative viscosity decrease of a cooling and hydrating mantle wedge, from i to f (see text). Note that the viscosity of incoming crust will tend to decrease (from basalt to sediment) with increasing amounts of sediments and/or with addition of water released from progressive sediment dehydration. Stars mark the inception of melting of basalt and sediments (after Kessel et al., 2005 and White et al., 2007, respectively).

(c) 2D sketch of slab penetration during subduction infancy, emphasizing the importance of fluid liberation from the slab. The dashed green line bounds the stability field of serpentine ("serp. front"; blue dots suggest that only part of this domain may be effectively hydrated). Fluid storage capacity of the mantle wedge decreases downwards (see section 3.2). Background isotherms are taken after 1 My from thermo-kinematic modelling (see supplementary material). Abbreviations: s: sediments (shown here in red, as in Fig. 1b), b: basaltic layer, g: gabbroic layer, m: mantle, serp.: serpentinite; (d) Black arrows outline evolving rheologies of the crust on top of the slab (basalt, then sediment) and of the mantle immediately above the slab (Fig. 4c) when the slab descends during subduction infancy. The rheological contrast across the plate interface between the basaltic crust and mantle wedge evolves from $\Delta\eta$ to $\Delta\eta'$ and $\Delta\eta''$. Evolution along the black arrows shows the existence of two rheological switches during subduction infancy, when slab crustal rocks reach viscosities comparable to that of the mantle wedge (dots 1a and 1b; see also Fig. 3a). The temperature range for the formation of HT and LT soles is indicated.

Published flow laws and material creep parameters used to compute the curves of figure 4b. *n*, *A*, *Q* and *m* correspond to the stress exponent, pre-exponential factor activation energy and grain size exponent, respectively (*calculated with X_{H2O}=0.05 wt%). DisGBS: dislocation-accommodated grain boundary sliding. See supplementary material for references.

Fig. 5

Figure 5

Model evolution for slab penetration and metamorphic sole formation during subduction infancy (2D sketches and abbreviations as in Fig. 4c; the dashed green line marks the downdip limit of the stability of serpentine, "serp."; the white arrow indicates exhumation): (a) strong interplate mechanical coupling due to the first rheological switch (i.e., when mantle wedge viscosity $\sim$ slab basalt viscosity). Resistance of the mantle wedge to slab penetration triggers the peeling of the slab and HT sole formation. Isotherms and depths are from thermo-kinematic modelling (see supplementary material). Stars indicate incipient melting of basalts and sediments (and plagiogranite formation; Rioux et al., 2013); (b) second rheological switch and LT sole formation. HT metabasalts metamorphosed deeper down in the locked zone are not returned as HT soles (see section 5.2.1). Some HT eclogites may get embedded in a softer mantle wedge and exhumed early in the subduction process; (c) the plate interface progressively 'unzips' by the downward extension of serpentinization until full decoupling. P-T-rheological conditions are such that LT eclogites form along the subduction zone but are only rarely exhumed (see section 5.2.1); (d) close-up view on the tectonic configuration along the plate interface during LT sole accretion, when partial exhumation of the HT sole (shown by the white arrow) juxtaposes it onto the LT sole. Accretion of the LT sole may correspond to the mechanical coupling of the sediments with the mantle above (second rheological switch; option 1) or to the mechanical coupling of the sediments with a progressively weakened mafic HT sole (option 2). See text for details. (e) progressive strain localization results in more superficial decoupling over time within the slab, so that accretion becomes restricted after a few My to shallow near-trench infill;

APPENDIX. SUPPLEMENTARY MATERIAL

A. Effective viscosities of plate interface material constrained by rock mechanics

Figure S1. Influence of strain rate on the effective viscosities of selected lithologies at two different temperatures (i.e., 500 and 650°C; same colors as in figure 4a, except for felsic granulite). Note that the respective positions of the dry mantle, basalt, quartz and serpentine remain unchanged for strain rates $> \sim 10^{14} \text{ s}^{-1}$. Note the stronger dependence on strain rate of serpentine and biotite schist, which are almost independent of temperature (as seen in Fig. 4a). Abbreviations: H07: Hilairet et al., 2007; Karato and Wu, 1993; K90: Kronenberg et al., 1990; RM87: Ranalli and Murphy, 1987; ST81: Shelton and Tullis, 1981; WK90: Wilks and Carter, 1990.

B. Thermo-kinematic modelling

Thermo-kinematic modelling (after Duprat-Oualid et al., 2013) was performed here in order to place first order constraints on the thermal regime of our tentative reconstruction of slab penetration into the mantle and metamorphic sole formation (Fig. 5). The advantage of such a 2D thermo-kinematic model, as described in detail in Duprat-Oualid et al. (Fig. S2; 2013), is that it includes a minimum of parameters (i.e., initial thermal ages of the oceanic lithosphere, convergence velocities and slab dips; Fig. S3), in contrast with thermo-mechanical modelling, which is beyond the scope of this study. It also provides a first grip on the depth and duration of the rheological switches outlined in our study (see Fig. S4 below).

1. Model design and numerical code description

The morphology of the model is shown in figure S2a. Incoming lower plate material, with a characteristic initial age for the oceanic lithosphere (T_{age}), is continuously buried at a constant convergence velocity (V) along a subduction plane with prescribed dip angle (θ), to simulate the subduction of an initially flat oceanic lithosphere down to the mantle. The model box is 85 km high, and the width of the model is adjusted depending on θ to ensure a constant grid resolution of 1 km in all models.

The initial temperature is computed following a half space oceanic geotherm equation (e.g., Turcotte and Schubert, 2002), expressing the temperature T as a function of depth (z). Such a thermal profile depends on the thermal properties of the rocks (i.e., k , ρ and Cp), on the thermal age T_{age} of the oceanic lithosphere and on the difference between the temperature of the mantle T_m and the surface T_s , fixed at 1350°C and 0°C, respectively. Thermal properties used both for this initial thermal profile and during the simulations are: $k = 2 \text{ W.m}^{-1}.\text{K}^{-1}$, $\rho = 3000 \text{ kg.m}^{-3}$ and $Cp = 1000 \text{ J.kg}^{-1}.\text{K}^{-1}$.

At each time step, the code solves the following heat thermal equation:

$$\rho \cdot C_p \cdot \frac{\partial T}{\partial t} = \frac{\partial}{\partial x} \left(k \frac{\partial T}{\partial x} \right) + \frac{\partial}{\partial z} \left(k \frac{\partial T}{\partial z} \right) + Q, \quad (\text{Eq. 1})$$

where ρ , C_p , and k are the density, the heat capacity and the thermal conductivity, respectively. Q , which corresponds to the heat production part (due, for instance, to radiogenic heat production or shear heating), is set to 0. This point is however discussed below and in the discussion section.

This equation (Eq. 1) is solved by using the implicit finite difference method on the Eulerian grid (e.g., Gerya, 2010). Temperature at the top of the model is fixed at 0°C, while the left and right sides of the model are subject to insulating boundary conditions (i.e., $\frac{\partial T}{\partial x} = 0$). The boundary condition at the bottom of the model is that of a constant flux (i.e., $\frac{\partial^2 T}{\partial z^2} = 0$). The temperature T computed on the nodes is then interpolated on markers and advected through the model by following the imposed velocity field (see Gerya, 2010 and Duprat-Oualid et al., 2013).

2. Parametric study

The influence of the convergence velocity V , subduction dip angle θ and initial age of the oceanic lithosphere T_{age} (controlling the initial thermal profile, Eq. 2) has been tested through a parametric study. For the sake of clarity, we focus the following description on the range of temperatures associated with HT sole formation (for which refined constraints on their P-T conditions of formation also exist; Fig. 3b).

Results show that the kinematic parameters (V, θ) control the time at which the tip of the slab reaches a given temperature (Fig. S2c), while the initial thermal age of the oceanic lithosphere controls the depth where this occurs (Fig. S2b). Considering a velocity of 3 cm.yr⁻¹ and a dip of 30° for the subducting slab ($V \cdot \sin(\theta)$ is 1.5 cm.yr⁻¹), a very low initial T_{age} is required to reach 700°C in less than ~2 My (Fig. S2b). This is why our reference experiment uses a T_{age} of 3 Ma. In such a

949 configuration, our models predict that the temperature of ~750°C will be reached at around 20 km
950 depths (Fig. S2d).

951

952 **3. Results from modelling**

953 The initial thermal age, convergence velocity and slab dip are set to 3 Ma, 3 cm.yr⁻¹ and 30° in
954 the reference model, so that the tip of the oceanic crust located on top of the slab reaches 750°C and
955 20 km depth after ~1.5 My (and 1000°C at ~25 km depth after 1.75 My; Fig. S2d). This
956 configuration is the one adopted in Figure 5.

957 Thermo-kinematic models constrain the evolution of temperature through time along the plate
958 interface for given depths, shown here at 10-20-30-40 km for the reference experiment (Fig. S3a).
959 T-time trajectories of evenly spaced incoming rocks (i.e., at the slab tip and then every 30 km away,
960 for points A, B, C and D; Fig. S1d) are shown on figure S3b.

961 The evolution of temperature through time along the plate interface and T-time trajectories (Fig.
962 S3) show that a rock starting to subduct 1 My after subduction initiation (point B; Fig. S4) will be
963 in the temperature range of formation of the HT sole and mafic/ultramafic rheological switch
964 (~750-850°C) between 2.8 and 3.2 My at 27-32.5 km depth. The depth and duration over which
965 incoming rocks remain in this temperature interval, for a range of realistic upper plate thermal ages
966 and slab dips (Fig. S4), is 25±7 km (across a few km on either side of the thrust) for no more than
967 0.3-0.4 My.

968

969 **4. Influence of shear heating.**

970

971 Shear heating (Hs) corresponds to the transformation of mechanical energy into heat during
972 deformation and depends on the strain rate and on the viscosity. For a shear zone with thickness h ,
973 exhibiting a homogeneously distributed shear velocity V and an effective mean viscosity η , Hs can
974 be expressed as (e.g., Duprat-Oualid et al., 2015):

975
$$Hs = \eta \frac{V^2}{h^2},$$

976 In our simulations, we can thus compute this heat production for a given viscosity and a given
977 strain rate as presented in figure S5. Results show that Hs strongly affects the thermal evolution
978 around shear zones, especially for high viscosity values. The temperature conditions for the
979 formation of the metamorphic sole are in this case located at shallower depth than in experiments
980 which do not include shear heating. This results are obtained for constant viscosity and do not
981 account for the T-dependency of viscosity: in nature, however, almost all materials (see Fig. 4b)
982 present a decrease in viscosity with increasing temperature. These simulations therefore provide an
983 estimate of the maximum influence of shear heating, reality being probably between situations
984 shown in figures S2d and S5.

985 The important result is that, even if shear heating highly modifies the thermal field evolution
986 around the shear zone, it does not alter the pattern of the isotherms. Figure S5 indeed shows that
987 whatever the viscosity of the shear zone (and therefore the amount of heat produced by shear
988 heating), the global “S-shape” of the isotherms, and therefore the existence of rheological switches,
989 is always reproduced. Consequently, although shear heating can impact the depth of metamorphic
990 sole formation, it does not affect the processes related to plate interface rheological switches that we
991 propose in this study.

Figure S2. Thermo kinematic modelling of the temperature field associated with slab penetration into the mantle during subduction infancy; (a) Set-up of the numerical model. The initial temperature field is flat and depends on the thermal age of the oceanic lithosphere (T_{age}). V corresponds to the convergence velocity; (b) and (c): Variations, as a function of time and initial oceanic T_{age} , of the depth (left panel) and burial velocity ($V \cdot \sin \theta$; right panel) required for the tip of the slab to reach the temperature of 700°C . Depths of metamorphic sole formation are chiefly controlled by the initial T_{age} of the oceanic lithosphere (left panel), while kinematic parameters control the time at which this happens (right panel); (d) Thermal structure of the reference model after 1.75, 2.75 and 3.75 Myrs, which was used in figure 5.

Figure S3. Thermal modelling of slab penetration during subduction infancy. (a) Evolution of slab temperatures along crust-mantle boundaries at depths of 10-20-30-40 km (thin curves). Red line: T-time trajectory of the surface temperature of point A (tip of the slab). Orange overlay: T range of HT sole formation. Incipient melting of basaltic crust is given for an average value between wet and dry MORB (Kessel et al., 2005). See text for deformation mechanisms (disGBS: dislocation-accomodated grain boundary sliding; Linckens et al., 2011a; Hirth and Kohlstedt, 2015); (b) Thick red lines give T-time trajectories for evenly spaced points along the top of the slab (A: slab tip; points A to E are spaced every 30 km; see Fig. S2d). Temperatures along the slab Moho are shown with dashed blue lines. Open black circles indicate when a given point enters the conditions of metamorphic sole formation (black arrows outline approximate duration under these conditions).

Figure S5. Influence of shear heating on the thermal evolution of the subduction zones. Plots are provided here after 2 My (see details in the supplementary material section 4 above). The top-left panel corresponds to the thermal field obtained for the reference model, with no shear heating. In the 3 others panels, heat production by shear heating is implemented assuming a shear zone thickness of 1 km and a constant viscosity (10^{20} , $10^{20.5}$ and 10^{21} Pa.s, respectively). As the viscosity of rocks is strongly temperature dependent (Fig. 4b), these simulations are not fully consistent but nevertheless useful since the viscosity values considered here lie in the range inferred from natural data (10^{20} Pa.s: Tasaka et al., 2013; 10^{21} Pa.s: Linckens et al., 2011). Black curves correspond to the 700 and 800°C isotherms. The black dot is located at a depth of 30 km for reference.
