3 ABSTRACT. We investigated the assembly of Gold nanoparticles (AuNPs) on Gold and Silicon  
4 sensors with two final objectives: (i) understanding the factors governing the interaction and (ii)  
5 building up a nanostructured piezoelectric immunosensor for diclofenac, a small-sized  
6 pharmaceutical pollutant. Different surface chemistries were devised to achieve AuNPs assembly  
7 on planar substrates. These surface chemistries included amines to immobilize AuNPs *via*  
8 electrostatic interaction, or a mixture of amines and thiols to covalently attach the AuNPs. We  
9 also generated PEG-amine terminated surfaces to benefit from the well-known non-biofouling  
10 properties of PEG-coated surfaces. The functional substrates and the resulting gold nanoparticle  
11 layers were characterized in detail by Surface IR, contact angle measurements and Scanning  
12 Electron Microscopy (SEM). The mechanism of adsorption is discussed herein considering the  
13 nature of the terminal groups and their charge at the pH of AuNPs adsorption. The coverage and  
14 the dispersion of AuNPs were strongly dependent on the anchoring points on the surfaces; the  
15 optimal were reached when the attachment layer offered multiple interaction points, in particular,  
16 for NH<sub>2</sub>/SH and PEG/NH<sub>2</sub> terminated surfaces, where the percentage of isolated particles was up  
17 to 78 %. In addition, PEG-coated surfaces led to a stable AuNPs layer resistant to ultrasounds  
18 and to further functionalization of the immobilized nanoparticles. These surfaces were used to  
19 engineer quartz crystal microbalance (QCM) biosensors for diclofenac detection. The AuNPs  
20 nanostructured substrates significantly enhanced the biosensor sensitivity as compared to planar  
21 substrates (up to 6 times higher). This enhancement presages a higher sensitivity in the  
22 competitive detection of diclofenac on these systems. More importantly, despite the  
23 biorecognition and the drastic regeneration conditions, SEM images show that gold nanoparticles  
24 layers are stable and reliable, which paves the way for their use as nanostructured platforms for  
25 multiple applications.

3 INTRODUCTION  
4

5 The assembly of gold nanoparticles (AuNPs) onto planar substrates has expanded tremendously  
6 over the last several decades, particularly in the biosensors field<sup>1-3</sup>. These nano-objects lead to  
7 dramatic improvements in the performance and sensitivity of biosensing devices owing to their  
8 plasmonic properties and to their efficiency as nanostructuring agents. The benefit from  
9 plasmonic properties of planar substrates decorated by gold nanoparticles is dramatic for  
10 techniques such as surface enhanced Raman spectroscopy (SERS) now widely employed for  
11 biosensing<sup>4-6</sup>. The interest in these nano-objects for signal enhancement in biosensors based on  
12 non optical techniques is more recent, yet it is growing fast. In the particular case of quartz  
13 crystal microbalance (QCM) biosensors, nanostructuring of the surface of the quartz crystal  
14 electrodes with AuNPs leads to an increase of the accessible surface area and by then the number  
15 of binding sites<sup>7-8</sup>. For DNA biosensors, nanostructuring by AuNPs results in a better  
16 attachment of the oligonucleotides to the surface, up to 10 times higher than on planar substrates,  
17 and therefore an increased capacity for nucleic acid detection<sup>9-11</sup>. The same trend was observed  
18 for antibody-based biosensors; despite the bigger size of these receptors, their density was  
19 improved while preserving affinity to their target<sup>12-14</sup>. All the same, antibody fragment based  
20 biosensors benefit from AuNPs assembly; higher sensitivity and overall better immunosensing  
21 performances were evidenced<sup>15-16</sup>.

22 Grafting of metallic particles on substrates is often done *a posteriori*, starting from colloidal  
23 solutions<sup>4</sup>. Commonly synthesized by the so-called “Turkevich Synthesis<sup>17</sup>,” –involving the  
24 reduction of Au ions by reducing agents such as citrate – gold nanoparticles are formed through a  
25 classical nucleation and growth process terminated by citrate ( $\text{Na}_3\text{C}_6\text{H}_5\text{O}_7$ ), which controls the  
26 nanoparticle size and morphology by acting as a surface functional layer or a capping agent, and

2  
3 preventing inter-particle aggregation through electrostatic repulsion. Prior to AuNPs deposition,  
4  
5 surfaces need to be covered with reactive functions, usually amines or thiols, to favour the  
6  
7 interaction with AuNPs through electrostatic or covalent bonds. Molecules commonly used at  
8  
9 this step are organothiols in the case of gold<sup>18-19</sup> or organosilanes for oxidized silicon and glass  
10  
11 surfaces<sup>20-21</sup>. More recently, polymer-based coating was applied to attach AuNP on planar  
12  
13 substrates<sup>22-23</sup>. Poly(ethylene glycol) (PEG) is particularly adapted to biosensing applications by  
14  
15 forming smooth and uniform PEG films that inhibit non specific adsorption<sup>24-25</sup> and provide a  
16  
17 high affinity to citrate-stabilized gold nanoparticles<sup>26-27</sup>. Once AuNPs are immobilized on a  
18  
19 substrate, although the citrate capping agent is well-suited as a native functional layer during  
20  
21 synthesis, substituting citrate, which is only bound loosely to the nanoparticle surface through  
22  
23 weak van der Waals interactions, by a more tightly bound and well-defined capping layer is  
24  
25 mandatory for further grafting of biomolecules or target and application in biosensing. For this  
26  
27 post-functionalization the organosulfur compounds represent perhaps the most widely practiced  
28  
29 route<sup>28-29</sup>. To withstand this post-functionalization, AuNP layers should also be stable over time  
30  
31 and their interaction with the surface strong enough to ensure that the nanoparticles remain  
32  
33 attached during further functionalization and upon utilization. Despite the huge interest in AuNP-  
34  
35 nanostructured substrates, the assembly of gold nanoparticles on surfaces and their post-  
36  
37 functionalization still rely on an approximate approach since the fundamentals of the chemistry  
38  
39 involved in the adsorption process are poorly understood<sup>20, 30-31</sup>.

40  
41 In this contribution, we investigated the mechanism of assembly and the stability of spherical  
42  
43 gold nanoparticles on functionalized silicon and gold substrates. To this purpose, we devised  
44  
45 different surface chemistries to establish the key-parameters in the attachment layer that  
46  
47 dominate the interaction with gold nanoparticles. Both gold and oxidized silicon substrates were  
48

3 modified by thiols and silanes to generate amine-terminated layers. Then, reaction of a thiol-  
4 terminated carboxylic acid with the grafted amines allowed us to generate mixed thiol/amine  
5 terminated layers. In addition, we utilized diamine-PEG cross-linked to acid and epoxy groups  
6 on gold and silicon, respectively, to compare the efficiency of these films to the previous ones.  
7  
8 The assembly of gold nanoparticles on these platforms was examined in depth by Scanning  
9 Electron Microscopy (SEM), focusing on the coverage and dispersion, and the impact of the  
10 attachment layers is discussed. We also investigated the influence of the post-functionalization  
11 agent (either an organothiol or a PEG) on the AuNP layers. Finally, the stable and well-dispersed  
12 layers are used to build piezoelectric immunosensors for the anti-inflammatory drug diclofenac  
13 and their efficiency was compared to planar surfaces. The stability of AuNP layer upon  
14 biorecognition and regeneration processes was eventually investigated by SEM.

## 34 EXPERIMENTAL SECTION

35  
36 **Materials:** Sodium citrate, gold(III) chloride trihydrate, 3-glycidyloxypropyltrimethoxysilane  
37 (GOPTS), tannic acid, N-ethyl-N'-(3-(dimethylamino)propyl)carbodiimide hydrochloride (EDC),  
38 cysteamine.HCl (CEA), diclofenac sodium salt, phosphate-buffered saline (PBS) pH= 7.4,  
39 poly(ethylene glycol) bis(amine) DAPEG<sub>68</sub> (MW= 3000 Da) , N-hydroxysuccinimide (NHS),  
40 11-mercaptoundecanoic acid (MUA), (3-aminopropyl)triethoxysilane (APTES) (99%), silicon  
41 wafers <111> and anti-mouse IgG (Fc specific) antibody produced in goat were purchased from  
42 Sigma–Aldrich. Poly(ethylene glycol) bis(amine) DAPEG<sub>45</sub> (MW = 2000 Da) was obtained from  
43 Huntsman (Rotterdam, Netherlands). Sodium dodecyl sulfate (SDS) was purchased from Fisher  
44 Scientific. The rabbit polyclonal anti-diclofenac serum was prepared in-house<sup>32</sup>, its analytical

2  
3 potential is detailed in reference <sup>33</sup>. Milli-Q water (18 MΩ, Millipore, France) was used for the  
4  
5 preparation of the solutions and for all washes. Experiments were carried out at room  
6  
7 temperature unless otherwise stated.  
8  
9

10  
11  
12 **Surface chemistry:** Silicon wafers cut into 1 x 1 cm pieces were cleaned following a procedure  
13 including several washing steps and treatment by hydrochloric acid / methanol 1:1 (v/v) for 1 h.  
14  
15 Reactive hydroxyl groups were generated by shaking wafers in sulfuric acid for 1 h. After  
16  
17 washing with water, the substrates were dried under nitrogen flow <sup>34</sup>. APTES was grafted by  
18  
19 immersing the wafers in a solution of silane in anhydrous toluene (50 mM) and heating at 75°C  
20  
21 for 24 h. Samples were washed twice, sonicated for 10 min in anhydrous toluene, dried under  
22  
23 nitrogen flow, and heated at 90°C for 2 h <sup>35</sup>. Surface sulfhydryl functions were generated by  
24  
25 exposing the wafers to a solution of MUA (10 mM in EtOH previously activated with NHS (2.4  
26  
27 eq.) and EDC (1.2 eq.)). Grafting of GOPTS was carried out by covering wafers with GOPTS  
28  
29 (100 μL) and avoiding exposure to the atmosphere by assembling two substrates face-to-face.  
30  
31 After 3 h, the sandwiches were separated and sonicated first in ethanol, then in methanol and  
32  
33 again in ethanol for 5 min each. They were dried under nitrogen flow and heated for 5 min at  
34  
35 85°C. Afterwards, the wafers were treated with molten DAPEG<sub>45</sub> (600 μL) and incubated at  
36  
37 98°C for 12 h in the sandwich format. The wafers were separated, sonicated in water for 15 min  
38  
39 and dried under nitrogen flow <sup>25</sup>.  
40  
41  
42  
43  
44  
45  
46  
47

48 Gold-coated sensors were immersed in a freshly prepared solution of CEA (10 mM in water) or  
49  
50 MUA (10 mM in EtOH) for 18–24 h. After washing with the same solvent, the CEA-treated  
51  
52 surfaces were dipped into a solution of MUA (10 mM in EtOH previously activated with NHS  
53  
54 (2.4 eq.) and EDC (1.2 eq.)) for 2 h. The MUA-treated surfaces were exposed to 150 μL of an  
55  
56  
57  
58  
59  
60

1  
2  
3 aqueous solution of NHS (2.4 eq.) and EDC (1.2 eq.) for 2 h to activate the carboxyl groups. The  
4  
5 surfaces were rinsed with the same solvent and dried under nitrogen flow. DAPEG<sub>45</sub>  
6  
7 immobilization was finally performed as described above. All the functional substrates were  
8  
9 stored in a dessicator.  
10  
11

12  
13  
14  
15 **Gold nanoparticles preparation and deposition:** Colloidal gold particles were prepared  
16  
17 according to the tannic acid method of Slot and Geuze<sup>36</sup>. To produce 100 mL of a 14 nm  
18  
19 diameter colloid solution, two stock solutions were prepared: solution A: 1 mL 1% (w/v) HAuCl<sub>4</sub>  
20  
21 and 79 mL water; solution B: 4 mL 1% sodium citrate, 0.025 mL 1% tannic acid and 16 mL  
22  
23 water. Solutions A and B were heated to 60°C under stirring then mixed. When the solution  
24  
25 turned red, the mixture was heated up to 95°C for a few minutes and cooled on ice. Colloidal  
26  
27 solutions were kept in amber glassware, stored in the refrigerator at 4°C and used within a  
28  
29 month. Modified substrates were dipped into the prepared colloid solution, with no further  
30  
31 dilution for 90 min under sonication (Elma, 90 W, 45 kHz), washed twice in water and dried  
32  
33 under nitrogen. Surfaces were finally immersed in a solution of CEA or DAPEG<sub>68</sub> (1mM in  
34  
35 EtOH) for 2 h to decorate the AuNPs with amino groups. The resulting substrates were stored in  
36  
37 a dessicator.  
38  
39  
40  
41  
42  
43  
44

45  
46 **Covalent grafting of Diclofenac:** Diclofenac (10 mM in dry DMF) was activated by treatment  
47  
48 with NHS (1.2 eq.) and EDC (1.2 eq.) for 150 min at room temperature. Then, the substrates  
49  
50 terminated by amino groups were dipped into the solution, shaken over night at room  
51  
52 temperature, washed for 15 min in water and dried under nitrogen flow. They were stored in a  
53  
54 desiccator.  
55  
56  
57  
58  
59  
60

1  
2  
3 **Binding of anti-diclofenac antibody:** The mixture of PBS and ethanol 9:1 was thoroughly  
4 degassed under vacuum (for 15 min) and used as carrier buffer in the flow system (flow rate  
5 25  $\mu\text{L min}^{-1}$ ). The sequence of injections was carried out as follows:  
6  
7

8  
9  
10 10-20 min flow of carrier buffer to stabilize the baseline signal; 10 min flow of 1/500 dilution of  
11 anti-diclofenac serum in PBS/EtOH; Washing with carrier buffer  
12  
13

14  
15 The regeneration buffer was a solution of 2 w% sodium dodecyl sulfate (SDS) in water/ethanol  
16 (9/1=v/v) at pH=2 (HCl).  
17  
18  
19

20  
21  
22 **Characterization techniques:** Transmission Electron Microscopy (*TEM*) measurements were  
23 performed using a JEOL JEM 1011 microscope operating at an accelerating voltage of 100 kV.  
24  
25

26  
27 The TEM grids were prepared as follows: Typically 1.5 mL of the colloid solution was  
28 centrifuged at 11200 g for 10 min to precipitate the particles. The colorless supernatant was  
29 discarded. The residue was re-dispersed in a suitable volume of water. 2  $\mu\text{L}$  of this particle  
30 suspension was dispensed on a carbon-coated copper grid and dried at room temperature. Gold  
31 nanoparticles size distribution was determined using ImageJ. Scanning Electron Microscopy  
32 (*SEM*) of the gold and silicon substrates covered with AuNPs was performed using a FEG SU-  
33 70 scanning electron microscope with a low voltage of 1 kV at a distance of 1.9 - 2.3 mm; the  
34 secondary electron detector "in Lens" was used. Images taken at different scales and in different  
35 regions of the samples were recorded. The particle densities were calculated by counting the  
36 particles in the SEM images (isolated and aggregates of 2, 3, 4, 5, 6, and > 6 particles) on a  
37 representative area of 2.3 – 2.5  $\mu\text{m}^2$ . For *Contact Angle measurements* static water contact  
38 angles were measured at room temperature using the sessile drop method and image analysis of  
39 the drop profile. The instrument, which uses a CCD camera and an image analysis processor, was  
40  
41  
42  
43  
44

59  
60

1  
2  
3 purchased from Krüss Optronic GmbH (Hamburg, Germany). The water droplet volume was 1  
4  $\mu\text{L}$ , and the contact angle ( $\Theta$ ) was measured 5 s after the drop was deposited on the sample. For  
5  
6  
7  
8 each sample, the reported value is the average of the results obtained on 3 droplets and the  
9  
10 overall accuracy in the measurements was better than  $\pm 5^\circ$ . **PM-IRRAS** spectra were recorded on  
11  
12 a commercial NICOLET Nexus FT-IR spectrometer. Details on the experimental set-up are  
13  
14 available in reference <sup>37</sup>. Sensor chips were made of borosilicate glass substrates (11 mm  $\times$  11  
15  
16 mm), coated successively with a  $2.5 \pm 1.5$  nm thick layer of chromium and a  $250 \pm 50$  nm thick  
17  
18 layer of gold (Arrandee, Werther, Germany). They were annealed in a butane flame to ensure a  
19  
20 good crystallinity of the topmost layers and dipped in a bath of absolute ethanol during 15 min  
21  
22 before adsorption. The Si wafers were analyzed by **GA-ATR-IR** immediately after their  
23  
24 preparation. GA-ATR-IR spectra (256 scans,  $4 \text{ cm}^{-1}$  resolution) were recorded on a Tensor 27  
25  
26 spectrometer (Bruker) equipped with a VariGATR accessory (Harrick Scientific, Pleasantville,  
27  
28 NY) and incidence angle set at  $60^\circ$ . Quartz Crystal Microbalance with dissipation measurements  
29  
30 (**QCM-D**) were carried out with a 4-channel dissipative quartz crystal microbalance (Q-Sense  
31  
32 E4) using AT-cut 5 MHz quartz crystals (QCM sensors, 14 mm diameter) coated with a 3-100 nm  
33  
34 layer of gold or a 50 nm  $\text{SiO}_2$  film (Lot-oriel) at  $22^\circ\text{C}$ . Prior to use, they were cleaned by ethanol  
35  
36 and dried under nitrogen flow. Experiments were carried out in flow-through conditions using a  
37  
38 peristaltic pump. Data were simultaneously acquired at the fundamental frequency  $F$  of 5 MHz  
39  
40 ( $N = 1$ ) and several overtone frequencies (15, 25, 35, 45, and 55 MHz, i.e.  $N = 3, 5, 7, 9$  and 11).  
41  
42  
43  
44  
45  
46  
47  
48 Two physical parameters are discussed: the resonance frequency and the dissipation. The  
49  
50 frequency change can be correlated to the mass of the adsorbed layer using the Sauerbrey  
51  
52 equation <sup>38</sup>:  $\Delta F = -N \Delta m / C_f$ , where  $C_f$  ( $= 17.7 \text{ ng cm}^{-2} \cdot \text{Hz}^{-1}$  at  $F = 5 \text{ MHz}$ ) is the mass-  
53  
54 sensitivity constant, and  $N$  is the overtone number.  
55  
56  
57  
58  
59  
60

## RESULTS AND DISCUSSION

**Synthesis and characterization of AuNPs:** Citrate-stabilized spherical AuNPs were selected for this work as their synthesis has reached a level of maturity allowing a precise control of their shape, size, and dispersion. The size and dispersion of the gold colloids prepared in this work were estimated from UV-visible spectroscopy and Transmission Electron Microscopy (TEM) analyses. UV-Vis spectra and TEM images are given in the supplementary material section. On the UV-Vis spectrum (Figure S1-a), a narrow resonance plasmon band was present at 520 nm, typical of a particle size around 15 nm<sup>39-40</sup>. This was confirmed by TEM images (Figure S1-b), mathematical treatment of the images showed a homogeneous particle size distribution with an average size of  $13.5 \pm 1$  nm. The AuNP concentration in the solution, estimated by two methods (see supplementary section) was  $3.6 \pm 0.2$  nmol L<sup>-1</sup>.

**Surface functionalization of Au and Si substrates:** Six different surface chemistries were devised to generate a layer of AuNPs on gold and silicon planar substrates as schematized in Figure 1. Adhesion layers either included amines to ensure a strong electrostatic interaction with citrate-stabilized AuNPs<sup>41</sup> or amines and thiols to covalently bind AuNPs through S-Au bonds. In addition, adhesion layers including NH<sub>2</sub>-terminated poly(ethylene) glycol) were built up to benefit from the well-known anti-biofouling properties of PEG-coated surfaces and prevent non specific adsorption during the immunosensing process<sup>27</sup>. We used a diamine-PEG (DAPEG<sub>45</sub>) with a molecular weight of 2,000 Da, since this medium size PEG has been previously shown to provide a homogeneous cover on Si wafers<sup>24, 26, 42</sup>.

**Figure 1** Surface functionalization strategies devised for immobilization of AuNPs on gold and silicon substrates and adopted nomenclature for substrates.

Amine-terminated surfaces were generated on gold and silicon using CEA and APTES, respectively. Mixed amine/thiol terminated layers were obtained by reacting MUA on the previous amine-terminated layers. MUA reacts with approx. 24 % of amine groups leading to layers with SH/NH<sub>2</sub> ratio ~1/4<sup>20</sup>. Amine-terminated PEG layers were built up by conjugating DAPEG to carboxy-decorated gold and epoxy-decorated silicon substrates that had been obtained by self-assembling of MUA and GOPTS, respectively (see Figure 1). The terminal carboxylic acid groups of MUA SAM on gold were converted into NHS esters by reaction with EDC and NHS prior to DAPEG grafting according to a previously published procedure<sup>25</sup>. The resulting surfaces are named according to the following nomenclature: Substrate (Au or Si) –

Terminal group (NH<sub>2</sub>, NH<sub>2</sub>/SH, or PEG) as depicted in Figure 1.

Prior to AuNPs immobilization, the functionalized substrates were characterized by contact angle measurements and surface IR. Table 1 summarizes the static water contact angle values measured for these substrates.

Table 1 Static water contact angle measurements

	Si		Au	
Clean	< 10°		46±2°	
1 <sup>st</sup> layer	APTES	GOPTS	CEA	MUA
	83±2°	51±1°	51±2°	59±2°
2 <sup>nd</sup> layer	APTES+MUA	PEG	CEA+MUA	PEG
	40±4°	43±2°	48±1°	40±4°

The initial clean (oxidized) silicon surface was very hydrophilic as expected by the strong oxidizing conditions applied to the samples before analysis to generate a high density of surface hydroxyl groups<sup>25</sup>. Silanization with APTES resulted in a very large increase of the contact angle from 15° to 83° due to the presence of more or less ordered aminopropyl chains<sup>35,43</sup>. Further covalent binding of MUA resulted in a drop of the contact angle to 40°. This increase of hydrophilic character may result from a better packing of the organic layer owing to Van der Waals forces between the longer hydrocarbon chains of MUA<sup>44</sup>. Silanization with GOPTS also led to an increase of contact angle from 15 to 51° as a result of organic group presence on the surface. Treatment with DAPEG slightly decreased the contact angle to 43° in agreement with the known hydrophilic character of PEG derivatives<sup>26</sup>. The same trend was observed for gold surfaces, i.e. an increase of the contact angle upon CEA or MUA grafting<sup>45</sup> and a decrease after DAPEG grafting consistent with the higher hydrophilic character expected for PEG-covered surfaces. The contact angle measured for Au-PEG was roughly the same as the one measured for Si-PEG, ~ 40°.

Surface IR, either in ATR mode for silicon substrates, or PM-IRRAS mode for gold substrates,

1  
2  
3 was used to characterize the molecular composition of the thin films deposited on both surfaces.  
4  
5 The recorded spectra are shown in the supplementary information section (Figures S2, 3, and 4)  
6  
7 together with the detailed band attributions (table S2). Briefly, for both substrates the  
8  
9 characteristic bands expected upon surface modification were observed. On Au-NH<sub>2</sub> and Si-NH<sub>2</sub>  
10  
11 the primary amine bands were present in the range 1660–1640 cm<sup>-1</sup> the ammonium group bands  
12  
13 around 1480 and 1571 cm<sup>-1</sup>. Upon MUA grafting the intensity of these bands was lower and  
14  
15 amide bands appeared giving evidence of the successful conjugation of activated acid to surface  
16  
17 amine groups. All the same, successful grafting of DAPEG on Au-MUA and Si-GOPTS  
18  
19 substrates was evidenced on both systems by the presence in the IR spectra of an intense band at  
20  
21 1110 cm<sup>-1</sup>, assigned to the intense C-O-C stretching mode of the PEG chains<sup>25, 46</sup>.

29 **Gold nanoparticles immobilization on functionalized surfaces:** The AuNPs layer attachment  
30  
31 to the surface must be strong enough to prevent desorption/release during the successive steps of  
32  
33 biosensor elaboration, test and regeneration. Therefore, ultrasounds were applied during AuNP  
34  
35 deposition, to remove loosely bound nanoparticles. In addition, we have previously observed that  
36  
37 applying ultrasounds during deposition of AuNPs on Si surfaces prevented the formation of  
38  
39 aggregates<sup>20</sup>.  
40  
41  
42

43 Scanning electron microscopy was used to estimate the coverage and dispersion of AuNP on the  
44  
45 functionalized surfaces. SEM images and graphical estimation of AuNPs density and dispersion  
46  
47 are shown in Figure 2. The fractional coverage was calculated by dividing the area covered by  
48  
49 the 2D projection of the spherical AuNPs on the surface by the total area of the surface<sup>47</sup>, results  
50  
51 are shown in table 2.  
52  
53

54  
55 The coverage and dispersion of the nanoparticles layers were highly dependent on the structure  
56  
57  
58  
59  
60

1  
2  
3 of the organic adhesion film. On Au-NH<sub>2</sub> surfaces (Figure 2-d), AuNPs were barely detectable.  
4  
5 Their absence is ascribable to the application of ultrasounds. Indeed, when the deposition was  
6  
7 repeated under gentle stirring, SEM images (Supplementary information section, Figure S5)  
8  
9 showed a small quantity (29 particles/μm<sup>2</sup>) of gold nanoparticles on the surface, which supports  
10  
11 the hypothesis of weak interactions between AuNPs and Au-NH<sub>2</sub> surface. Conversely, a  
12  
13 relatively high density of gold nanoparticles (510±15 x NP/μm<sup>2</sup>) was observed on Si-NH<sub>2</sub>  
14  
15 substrates (Figure 2-a). This difference observed between Si and Au can be understood by  
16  
17 considering the difference in amine coverage on the two substrates: while CEA forms a  
18  
19 monolayer of more or less ordered thiols on gold<sup>48</sup>, APTES condensation on silica-like  
20  
21 substrates leads to a low amine coverage<sup>35</sup>. Therefore on Au-NH<sub>2</sub> substrates only amine groups  
22  
23 are present whereas on Si-NH<sub>2</sub> both silanols (Si-OH) and NH<sub>2</sub> groups are present. Moreover, at  
24  
25 the acidic pH of AuNPs solutions (pH=5.4), amino groups on Au-NH<sub>2</sub> are mostly positively  
26  
27 charged, (pK<sub>a</sub> (CEA) =8.3<sup>49</sup>), therefore, their interaction with AuNPs can be envisioned mainly  
28  
29 through electrostatic bonds with negatively charged citrate ligands. Whereas on APTES modified  
30  
31 surfaces, pK<sub>a</sub>=7.6<sup>50</sup>, and though ammonium species dominate, they coexist with silanol groups  
32  
33 that are negatively charged at this pH (silica PZC=2<sup>51</sup>). Silanulates may be involved in AuNP  
34  
35 interaction with the surface as they can replace citrate ligands and directly interact with gold.  
36  
37 Therefore, these cooperative interactions on Si-NH<sub>2</sub> would explain the huge difference observed  
38  
39 with Au-NH<sub>2</sub>. Note that despite this cooperative interaction, the coverage observed on Si-NH<sub>2</sub>  
40  
41 layers was the lowest of all the silicon substrates under study (Figure 2 and Table 2).

**Figure 2** SEM images taken after AuNPs immobilization on the functionalized surfaces (a-f) and the resulting surface coverage (g)

1  
2  
3 After conjugation of MUA to the amine-terminated surfaces, the Si-NH<sub>2</sub>/SH substrates exhibited  
4 a higher coverage of AuNPs (Figure 2-b). For Au-NH<sub>2</sub>/SH the improvement could not be seen on  
5  
6 Figure 2-e, but again when the deposition was done without applying ultrasounds (Figure S5,  
7  
8 Supplementary section) AuNPs coverage was clearly improved compared to on Au-NH<sub>2</sub>. This  
9  
10 result corroborates the efficiency of cooperative interactions towards AuNPs immobilization,  
11  
12 here through Sulfur/Gold and ammonium/citrate interactions. On Si-NH<sub>2</sub>/SH, the fractional  
13  
14 coverage in AuNPs reached 0.20 (see Table 2). However, the increase in AuNPs coverage on Si-  
15  
16 NH<sub>2</sub>/SH substrates slightly worsen their dispersion, the percentage of isolated particles was  
17  
18 lowered to 62% and few aggregates were observed (Figure 2-b and g).  
19  
20

21  
22 The best dispersion of AuNPs and the highest surface coverage were observed for the PEG-  
23  
24 functionalized substrates, Si-PEG and Au-PEG (Figure 2- c and f). Both systems showed 78% of  
25  
26 isolated particles and fractional coverage of 0.14 – 0.18 (Table 2). This difference with the  
27  
28 previous substrates may result from the swelling properties of PEG films that make them capable  
29  
30 of capturing citrate-stabilized AuNPs<sup>27</sup> and trapping them by displacement of loosely bound  
31  
32 citrate ligands and creation of multidentate interactions between the PEG chains and the Au  
33  
34 atoms of the AuNPs<sup>26</sup>. This effect cooperates with the terminal amino group of the PEG chains  
35  
36 that acts by electrostatic interaction with citrate ligands to stabilize the nanoparticle layers.  
37  
38 Surprisingly, despite the thick layer of PEG (1.7 nm<sup>25</sup>), the substrates and/or the organic  
39  
40 underlayers influence the coverage, as the value is 24% lower on Au-PEG than on Si-PEG.  
41  
42 Nevertheless, though all the coverage reported in Table 2 may look low, one must keep in mind  
43  
44 that they in the same range than the data reported in the literature where the deposition and  
45  
46 washing conditions were less drastic, (0.15 -0.25)<sup>19, 41, 47</sup>. This limit is determined by the citrate  
47  
48 ligands co-adsorbed with AuNPs that maintain an electrostatic repulsion between adsorbed

14 To summarize this part, offering multiple anchoring points and cooperative interactions  
15 improved the coverage and dispersion of gold nanoparticles at the surface of gold and silicon  
16 planar substrates. These systems also show a resistance to leaching upon sonication which should  
17 make them suitable for further functionalization. The PEG layers provided an excellent  
18 dispersion on both substrates (78%). In what follows, we investigate for Si-PEG and Au-PEG  
19 substrates the stability of the AuNP layers upon post-functionalization, diclofenac biosensing and  
20 under the drastic regeneration conditions.

31 **Post-functionalization of gold nanoparticle layers:** The use of the AuNPs-modified platforms  
32 for biosensing requires the exchange of the surrounding citrate ligands by reactive functions that  
33 will be used to further construct the biosensing layer. Mastering this step is important because the  
34 AuNPs layer is mobile and ligand exchange may lead to particle aggregation or leaching from  
35 the support<sup>54-55</sup>. Two reagents were utilized for post-functionalization: CEA and PEG<sub>68</sub>, both  
36 introduce primary amine groups for further anchoring of diclofenac *via* its carboxylic acid  
37 function (see molecular structure in **Figure 5**). These post-functionalization treatments were  
38 applied to AuNP arrays deposited on PEG-coated silicon and gold substrates. The density and  
39 dispersion of AuNPs was then estimated by SEM. Representative images and their mathematical  
40 treatment are shown in Figure 3. As expected, post-functionalization modified the AuNP  
41 dispersion and coverage. On both substrates, the overall coverage was slightly lowered.

**Figure 3** SEM images (a-d) and AuNP densities (e) for Si-PEG-AuNP post-functionalized by CEA (a) or PEG (b) and Au-PEG-AuNP post-functionalized by CEA (c) or PEG (d)

Post-treatment of Si-PEG-AuNP substrates by CEA or DAPEG induced both a significant

1  
2  
3 desorption of particles (up to 30% with CEA) as well as aggregation. This behavior may be  
4 explained by the fact that, since the fractional coverage of AuNP on Si-PEG was higher than 0.15  
5 established as the upper limit determined by Grabar et al.<sup>41</sup> for 15-nm diameter citrate-capped  
6 AuNPs, the exceeding AuNPs were probably more loosely bound and/or mobile so that further  
7 treatment with a weak ligand like DAPEG favored aggregation whereas further treatment with a  
8 stronger adsorbate like CEA led to both aggregation and desorption. Similar desorption was  
9 previously reported on APTES-coated silicon upon treatment with CEA and explained by the  
10 positive charge of nanoparticles upon citrate ions replacement by CEA molecules that led to  
11 repulsion from the positively charged APTES-coated surface<sup>52,55</sup>. Conversely, post-  
12 functionalization of Au-PEG-AuNP by CEA or DAPEG did only marginally affect the overall  
13 particle density. This is in line with the fractional coverage being lower than 0.15, and therefore  
14 the probable absence of loosely bound particles on this surface. Furthermore, particle  
15 aggregation was only induced by CEA. In this situation, repulsion due to negative charges of  
16 citrates was no longer effective and aggregates formed<sup>53</sup>. On the whole, post-treatment on Au-  
17 PEG-AuNP by DAPEG allowed maintaining a high density of NP as well as a good dispersion.  
18 The nanostructured Si-PEG-AuNP and Au-PEG-AuNP substrates post-functionalized with  
19 DAPEG were further selected to build up a piezoelectric immunosensor for the anti-  
20 inflammatory drug diclofenac.

46 **Anti-diclofenac antibody recognition, specificity and reversibility:** Diclofenac was covalently  
47 bound through its carboxylic acid function to the PEG amino groups of the nanostructured gold  
48 and silicon sensors and recognition of anti-diclofenac antibody was investigated by QCM-D as  
49 depicted in Figure 4. QCM was also used to assess the specificity of recognition towards non  
50 specific anti-mouse IgG (Supplementary section, Figure S6) as well as the reversibility of the  
51  
52  
53  
54  
55  
56  
57  
58  
59  
60

haptent / antibody interaction (Supplementary section, Figure S7). In addition, to determine whether nanostructuring benefits to target recognition, the same experiment was run on flat silicon and gold substrates modified by GOPTS-PEG and MUA-PEG, respectively (Figure 4).

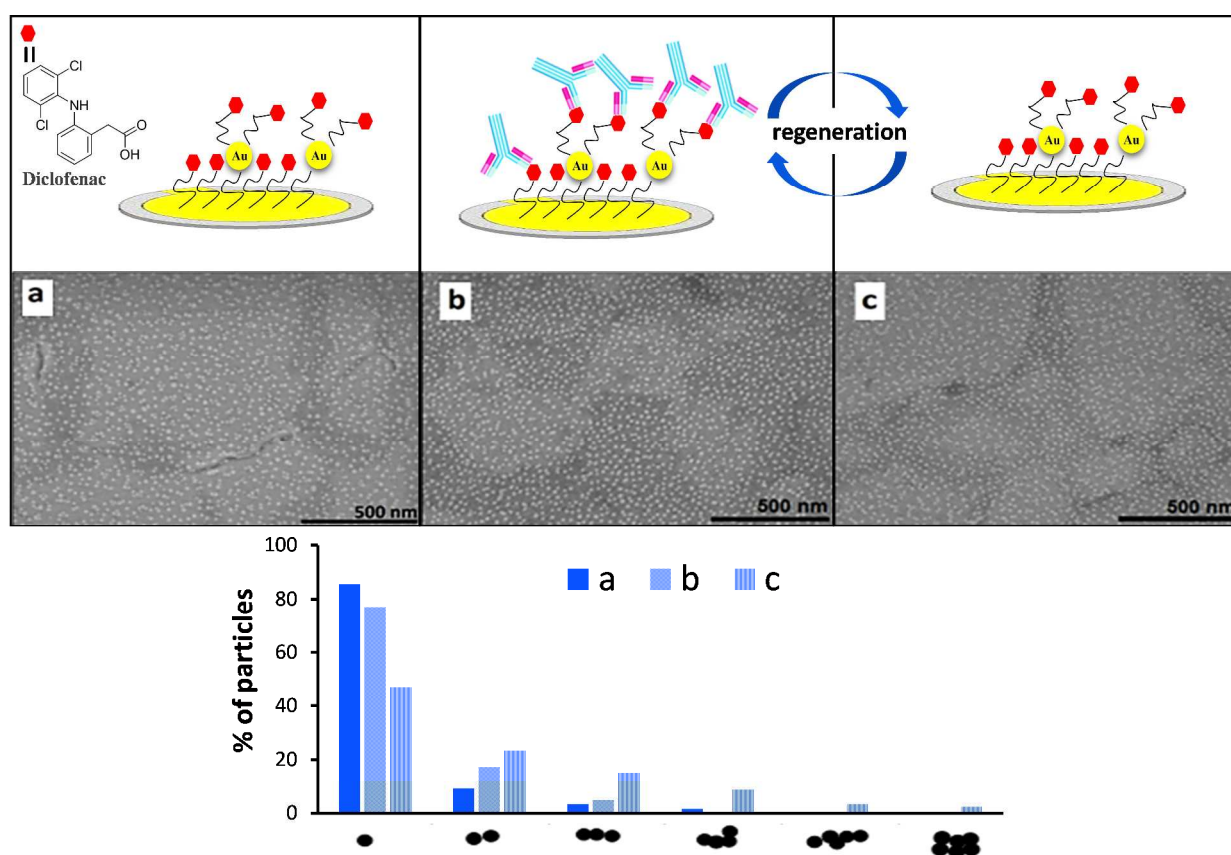

**Figure 4** Frequency and dissipation shifts monitored during capture of anti-diclofenac antibody and washing with carrier buffer with the 4 different immunosensors

Injection of non-specific antibody had no influence on the resonance frequency (Figure S6). Conversely, injection of anti-diclofenac antibody resulted in an immediate decrease of the resonance frequency of the 4 sensors confirming the recognition of the specific anti-diclofenac antibody by the capture layer comprising diclofenac (Figure 4). The magnitude of the shift ( $\Delta F$ ) as well as the rate of frequency change  $d\Delta F/dt$  were highly dependent on the nature of the sensing layer. On all systems, applying a regeneration buffer (pH=2) led to the release of the captured antibodies and return to the initial frequency (Figure S7).

We also analyzed the AuNPs layers by SEM to establish the possible effect of

immunorecognition and regeneration on their dispersion and coverage. The SEM images in Figure 5 show that the gold nanoparticles layer was remarkably stable after the biorecognition step and even after the drastic regeneration conditions at acidic pH. No change was recorded upon anti-diclofenac binding to the surface. Upon regeneration, the drastic conditions applied led to a decrease in nanoparticle dispersion, yet, only small aggregates were formed and less than 15% of AuNP formed aggregates larger than 4 units. The regeneration process needs to be optimized to further limit its impact on AuNP dispersion.

**Figure 5** Reversible immunorecognition scheme and SEM images and data of Au-PEG gold nanoparticles platforms post-functionalized with PEG<sub>68</sub> at the successive stages of the immunoreaction

Mass uptakes  $\Delta m$  were calculated from the frequency shifts by applying the Sauerbrey equation

1  
2  
3 since dissipation shifts were lower than  $1 \times 10^{-6}$  during antibody capture (Table 3). The QCM  
4  
5 responses in terms of  $\Delta F$  and  $d\Delta F/dt$  were significantly larger for the 2 nanostructured sensor  
6  
7 chips in agreement with the increase of specific surface brought by the layer of AuNPs. Clearly,  
8  
9 the two flat sensors had lower antibody binding capacity than the nanostructured ones. Before  
10  
11 washing with buffer, the increase was over 120% for both substrates, i.e. more than 6 times  
12  
13 higher than on flat surfaces. After washing, the input of nanostructuring was still important, 32  
14  
15 and 48% for silicon and gold, respectively. The origin of this enhancement may be geometrical  
16  
17 as the nanostructured sensors display a higher specific area than the flat ones. Knowing the  
18  
19 surface coverage in AuNPs and their mean size, the increase of accessible surface area can be  
20  
21 readily estimated. We have done these calculations depending on the exposed height of AuNPs  
22  
23 (i.e. how the AuNPs are actually embedded in the organic film). The increase in area ranged from  
24  
25 17 to 33% for the Si sensor (with 1073 particles/ $\mu\text{m}^2$ ) and from 13 to 26% for the Au sensor  
26  
27 (with 833 particles / $\mu\text{m}^2$ ). Alternatively, the surface topology of nanostructured sensors may also  
28  
29 favor the accessibility of the immobilized diclofenac ligand towards its antibody further  
30  
31 enhancing the geometric benefit of nanostructuring.  
32  
33  
34  
35  
36  
37  
38  
39  
40

41 **Table 3** QCM data for flat and AuNPs nanostructured surfaces

	Gold		Silicon	
	Flat	Nanostructured	Flat	Nanostructured
$-\Delta F_5$ (Hz)	11.8	$17.5 \pm 1$	12.5	$16.5 \pm 0.5$
$\Delta m/A$ (ng/cm <sup>2</sup> )	208	$310 \pm 18$	222	$293 \pm 9$
$\Gamma(\text{exp})$ (pmol.cm <sup>-2</sup> )*	1.4	2	1.5	1.95
Increase (%) before washing	---	128	---	124
Increase after washing (%)	---	48	---	32
$-d\Delta F/dt$ (Hz.s <sup>-1</sup> )	0.016	0.077	0.019	0.088

42  
43  
44  
45  
46  
47  
48  
49  
50  
51  
52  
53  
54  
55 Furthermore, the nanostructured surfaces on a silicon or gold substrates gave very similar  
56  
57 responses in QCM. The amount of anti-diclofenac antibodies recognizing the target differs little  
58  
59  
60

1  
2  
3 despite a difference in the total density of AuNPs greater than 20% for silicon substrates. This  
4  
5 result corroborates the assumption that increasing the surface area is the one and only reason of  
6  
7 the improved performances of nanostructured immunosensors and abounds and towards a greater  
8  
9 contribution granted by the new surface topology and the increased accessibility of the target.  
10  
11 This result thus also proves that, at this stage, the influence of the substrate is limited which  
12  
13 paves the way for a generalization of this surface chemistry to other substrates by expecting the  
14  
15 same performances.  
16  
17  
18  
19

20  
21 To conclude this part, AuNPs layers led to a significant enhancement in the biosensor sensitivity.  
22  
23 This enhancement presages a higher sensitivity in the competitive detection of diclofenac on  
24  
25 these systems. More importantly, despite the biorecognition and the drastic regeneration  
26  
27 conditions, gold nanoparticle layers were stable and reliable, which paves the way for their use  
28  
29 as nanostructured platforms for various applications.  
30  
31  
32  
33

## 34 35 CONCLUSION

36  
37 Different surface chemistries were devised to generate layers of gold nanoparticles (AuNPs) on  
38  
39 gold and silicon planar substrates. Adhesion layers either included alkyl chains or poly(ethylene  
40  
41 glycol) (PEG) and were terminated by amines or mixed amine and thiol groups. The assembly of  
42  
43 gold nanoparticles on the functionalized substrates was studied in depth by Scanning Electron  
44  
45 Microscopy. The highest coverage and dispersion were reached when gold nanoparticles were  
46  
47 deposited on adhesion layers offering multiple anchoring points and cooperative interactions.  
48  
49 These systems showed a resistance to leaching upon sonication which made them suitable for  
50  
51 further functionalization. Adhesion layers including PEG motifs provided an excellent coverage  
52  
53 and the best dispersion on both Si and Au substrates (78%). These layers were post-  
54  
55  
56  
57  
58  
59  
60

1  
2  
3 functionalized using either PEG-diamine or cysteamine to exchange the surrounding citrate  
4  
5 ligands by reactive functions that will be used to further bind the bioreceptors. This step slightly  
6  
7 decreased the coverage in gold nanoparticles, particularly on silicon substrates, but the use of  
8  
9 PEG-diamine better preserved the dispersion of gold nanoparticles. The resulting layers were  
10  
11 successfully used to build up a piezoelectric immunosensor for the anti-inflammatory drug  
12  
13 diclofenac. They were sensitive and specific to diclofenac antibody. Compared to planar  
14  
15 surfaces, they showed a significant enhancement in the biosensor sensitivity, up to 6 times the  
16  
17 signal recorded for planar substrates. More importantly, despite the biorecognition and the drastic  
18  
19 regeneration conditions, QCM sensors covered with gold nanoparticle layers were stable and  
20  
21 reusable with a preserved coverage and dispersion, which paves the way for their use as  
22  
23 nanostructured platforms for various applications.  
24

## 30 SUPPORTING INFORMATION

31  
32

33 Gold nanoparticles characterizations. IR characterization of functionalized surfaces. Gold  
34  
35 nanoparticles deposition. QCM data.  
36  
37  
38

## 39 ACKNOWLEDGEMENTS

40  
41

42 We would like to thank the DIM Analytics and Region Ile-de-France for M. Ben Haddada PhD  
43  
44 scholarship. This work was also co-financially supported by ANR (Agence Nationale de la  
45  
46 Recherche) and DFG (Deutsche Forschungsgemeinschaft), ANR-DFG program, project  
47  
48 NArBioS, Grant no: ANR-11-INTB-1013.
