16 Abstract:

17 Invasive macroalgae form a substantial component of marine invaders at a global level. However, it
18 is poorly understood how the complex interactions between local environmental conditions and life
19 cycle dynamics contribute to invasion success from a mechanistic viewpoint. The aim of this study
20 was to use a model (UndariaGEN) that incorporates a detailed representation of the individual
21 heteromorphic life history stages (sporophytes and gametophytes) of the species in order to explore
22 how interactions between these components contribute to the overall population dynamics. The
23 latest version of the model was validated against field data from a real-life population in Brittany,
24 France. This was followed by an assessment of the role of temperature limitations in determining its
25 potential global range and then a more detailed examination of how environmental factors affect
26 the life cycle dynamics of *U. pinnatifida* across a range of conditions characteristic of European
27 populations. In terms of both relative abundance and recruitment, the model matches closely the
28 patterns observed from field studies in Brittany, France ($R^2=0.98$ respectively). Furthermore, the
29 model predicted theoretical temperature limits for growth (9.1 - 22.5°C) match closely the actual
30 current global range limits for the species (9.5 - 22.4°C) reported in the literature. In addition, the
31 size of the species' ecological niche is shown to be directly related to the amplitude in seasonal
32 variation of temperature. This demonstrates that *U. pinnatifida* has a wider ecological niche in
33 conditions of high seasonality; this finding is consistent with theories that propose the
34 heteromorphic life cycle may have evolved as an optimal growth strategy for highly seasonal
35 environments.

36 **Key words:** Macroalgae, seaweed, life cycle schedule, individual-based model, agent-based model,
37 ecological niche, species distribution

38 **1. Introduction**

39 Ecological niche models (ENMs) (and related species distribution models, SDMs) are
40 commonly used to predict the potential range limits of invasive species based on their ecological
41 niche characteristics in their native range (Peterson 2003). These approaches can be used to produce
42 accurate habitat suitability maps assuming that ecological niches represent long-term stable
43 constraints on a species' potential geographic range (Marcelino, Verbruggen 2015). Most of these
44 approaches are correlative in nature, by statistically linking spatial environmental data to species
45 distribution records. However, attempts have also been made to incorporate some mechanistic links
46 between the functional traits of organisms and their environments into SDMs (Kearney, Porter
47 2009). The addition of physiological information can enable more robust predictions of range shifts,
48 particularly in novel or non-equilibrium contexts such as invasions or in response to environmental
49 change, by taking into account niche shifts during biological invasion (Broennimann et al. 2007;
50 Urban et al. 2007).

51 In this study, an individual-based modelling approach was used to represent the population
52 dynamics of the study species from a bottom-up perspective (DeAngelis, Gross 1992; Grimm,
53 Railsback 2005). This approach means that the individuals of the population are explicitly modelled
54 with individual growth rates and environmental response parameters as opposed to assuming global
55 population averages. This approach allows one to differentiate between the responses of the various
56 life history stages of the species. This is particularly important among species with heteromorphic
57 life cycles consisting of more than one alternating stage or phase. These are characterised by life
58 history stages that often differ in their growth parameters, ecological niches and physical properties
59 (Ebenman 1992; Eckert 2003; Thornber 2006). For example, in the case of many kelp species, the
60 gametophyte and sporophyte stages can differ in their genetic properties (haploid versus diploid),
61 size (microscopic versus macroscopic) and ecophysiology (temperature response profiles,
62 photosynthetic properties) (Morita et al. 2003a, b). For this study, an updated version of an

63 individual-based model framework which we previously developed, called UndariaGEN (Murphy et
64 al. 2016a), was used to investigate the population dynamics of the invasive kelp species *Undaria*
65 *pinnatifida* in a coastal environment.

66 *Undaria pinnatifida* is native to the coastal regions of eastern Asia, including Japan, Korea
67 and China, where it is commonly cultivated for culinary purposes (Ohno, Matsuoka 1993; Shao-jun,
68 Chao-yuan 1996). This edible seaweed was accidentally introduced to Europe in the 1970's in the
69 Étang de Thau, France, followed by deliberate introduction for cultivation purposes in Brittany,
70 France in 1983 (Daguin et al. 2005; Floc'h et al. 1991; Voisin et al. 2005). Subsequent to these
71 introductions it has expanded its range in Europe, invading artificial and natural coastal habitats and
72 extending from southern Italy in the south to the United Kingdom and Ireland in the north (Cecere et
73 al. 2000; Minchin, Nunn 2014; Peteiro 2008). Furthermore, it has also arisen as an invasive threat in
74 other regions of the world such as New Zealand and North America (Hay, Luckens 1987; Silva et al.
75 2002). Its ability to colonize artificial and disturbed habitats, its high fertility and its fast-growing
76 strategy are among the characteristics that explain its ranking as the third most invasive seaweed, in
77 a species trait analysis of 113 introduced macroalgae, in Europe (Nyberg, Wallentinus 2005).

78 The annual (or bi-annual) life cycle of *U. pinnatifida* is typical of brown kelp seaweeds with
79 two heteromorphic phases: a microscopic haploid gametophyte stage and a large (1-3 m in length)
80 diploid sporophyte stage (Clayton 1988; Thornber et al. 2004; Wallentinus 2007). These forms differ
81 in their growth requirements and responses to environmental factors such as light and temperature
82 (Morita et al. 2003a, b). The gametophyte stage is likely to facilitate the introduction steps and
83 subsequent spread through ballast water or as epiphytes on ship hulls and oyster shells (Mineur et
84 al. 2007; Mineur et al. 2006). Gametophytes are also capable of delaying their development possibly
85 forming a 'gametophyte bank', analogous to seed banks in terrestrial plants (Carney, Edwards 2006).
86 However, despite their importance in influencing the overall population dynamics at both local and

87 regional scales and thus their critical role in invasion success (Couceiro et al. 2013; Edwards 2000),
88 gametophytes are surprisingly hardly considered directly in empirical or theoretical studies.

89 The aim of this project was to use a model that incorporates a detailed representation of the
90 life history stages of *U. pinnatifida* with individual gametophytes and sporophytes represented as
91 autonomous agents with independent behaviour. The effects of environmental parameters such as
92 light and temperature on the growth and development of these stages could then be parameterised
93 independently for each stage, using empirical data from the literature, thus allowing population
94 behaviour to be traced back to the individual components. Three seasonally-variable environmental
95 parameters, which have been shown to play a key role in determining the growth potential of *U.*
96 *pinnatifida*, were examined: light availability, water temperature, and day length (or the photo-
97 periodic effect) (Báez et al. 2010; Campbell et al. 1999; Choi et al. 2007; James et al. 2015; Thornber
98 et al. 2004). There are extensive literature studies on the impact of these abiotic factors on
99 individual growth stages of *U. pinnatifida* (Choi et al. 2005; Morita et al. 2003a, b; Pang, Lüning 2004;
100 Pang et al. 2008; Shao-jun, Chao-yuan 1996). However, our understanding of the complex spatio-
101 temporal interactions between these factors and the microscopic and macroscopic stages of the life
102 cycle is limited.

103

104 **2. Methods**

105 A detailed description of the underlying model framework and the technical processes
106 involved in its design and parameterisation have been published previously (and presented with
107 updates in Appendix I) (Murphy et al. 2016a). For this study, we upgraded this model and focus on a
108 case study analysis using the model to examine the role of environmental conditions in determining
109 the current range of *U. pinnatifida* in Europe. The model has two measures of invasive potential: (a)

110 the traditional measures of population growth (changes in abundance and recruitment over time),
111 and (b) temporal changes to the seasonal schedule of recruitment of the various life history stages.

112 Therefore, in order to factor in these differences between life history stages and between
113 individual sporophytes and gametophytes the IBM approach was chosen. The environment is
114 modelled as a spatially-explicit, discrete two-dimensional grid in order to take into account
115 heterogeneities in the physical surroundings (at a spatial resolution of 0.25 m²). Meanwhile, time is
116 represented as discrete time steps with environmental parameters such as temperature and light
117 levels updated on a daily basis. This is to enable seasonal changes in the water conditions to be
118 accounted for and the growth responses of the agents to be updated at a relatively fine-grained
119 scale.

120 A broad technical overview of the model is included in Appendix I for reference. In the
121 following sections, we highlight the key changes made for the latest version of the model, developed
122 for this study. This upgraded version (v0.6.4) is available under a GNU General Public License Version
123 3 on the GitHub repository hosting service (<https://github.com/murphyjtm/undariaGEN>) (Murphy
124 2016).

125

126 *2.1. Sporophyte and gametophyte agents*

127 The IBM approach involves a bottom-up modelling technique whereby the main components
128 simulated are the individual life history stages, in this case the diploid sporophytes and haploid
129 gametophytes of the *U. pinnatifida* life cycle. Each individual sporophyte or gametophyte is
130 represented as an independent agent in the model with its own set of unique parameters (e.g.
131 growth rate, temperature response curve, etc.). Individual variability is an important component of
132 an IBM model and therefore a Mersenne Twister random number generator is used to vary the

133 growth properties for each individual agent (by sampling from a normal distribution around a
 134 population mean) (Matsumoto, Nishimura 1998).

135 Depending on the type of the agent (sporophyte or gametophyte), the behaviour and responses
 136 to local environmental parameters are calculated based on a different set of sub-models, unique to
 137 each agent type, which are fitted to ecophysiological data gathered from the literature (see
 138 Appendix I). At each time step, the growth rate of each agent is calculated separately according to its
 139 type (gametophyte or sporophyte), its own internal state (size, maturity, etc.), and the local
 140 environmental conditions (light, temperature, day length) at that point in space and time. The test
 141 simulations involved up to 3.0×10^5 agents growing concurrently and independently interacting with
 142 their environment and each other. Execution time was approximately 15 minutes per simulated year
 143 (on a quad-core Intel Xeon E3 1270 @3.4GHz desktop computer) The results were then aggregated
 144 and population-averaged results, which are an emergent property of all the agents interacting
 145 together, were collected for further analysis and presentation.

146

147 2.2. Modification 1: Calculation of photosynthetically available radiation

148 In the current and the previous versions of the model, the growth of agents is determined by
 149 the availability of light (since they depend on photosynthesis). In the model, there is a parameter for
 150 the light attenuation coefficient for photosynthetically available radiation (K_{dPAR}) which determines
 151 the amount of light attenuation, with increasing depth in the water column (Saulquin et al. 2013).
 152 This is used to calculate the residual energy available for photosynthesis by *U. pinnatifida* agents,
 153 depending on their depth, according to the following equation:

$$E(z) = E(0)e^{-zK_{dPAR}} \quad (1)$$

154 where z is the depth (m) of the seaweed below the water surface, $E(0)$ is the level of irradiance at
 155 the water surface, and $E(z)$ is the energy available for photosynthesis at depth z . For the case studies

156 in this paper, the depth (z) was set to 1.0 m and the attenuation coefficient (K_{dPAR}) to 0.4 for
157 conditions representative of the coastline of Brittany, France (Saulquin et al. 2013).

158 In the latest version of the model, an additional parameter has been incorporated to
159 represent scale effects on photosynthetic performance between individual plants and communities.
160 It has been demonstrated that the light saturation point (I_k) for macroalgal communities can be
161 several times higher than for individual thallus pieces tested in the laboratory (Binzer, Middelboe
162 2005). Therefore, in order to make a more realistic representation of natural conditions, we have
163 included an additional parameter to vary the light saturation point according to the community
164 structure. For the test cases described in this paper, this value was calculated by fitting to field data
165 collected from Brest harbour, France (see appendix Table S1). This involved varying the light
166 saturation factor from 1.0 (no competitive inhibition of light) to 10.0 (high saturation point due to
167 complex community structure) and comparing the R^2 values. A value of 3.3 resulted in a seasonal
168 pattern of recruitment that most closely matched the natural population in Brest (Fig. 1).

169

170 *2.3. Modification 2: Seasonal effects on juvenile mortality among sporophytes*

171 The death of a sporophyte agent is determined either when it reaches the natural end of its
172 lifespan, assumed to be after it has matured and released all its spores, or through premature death
173 or removal. Field studies have shown that up to 70% of sporophyte recruits die or are dislodged
174 within one month of their appearance (Voisin 2007). Therefore, premature death (by various means
175 such as competition or physical dislodgement) represents a significant proportion of the deaths in a
176 population. To account for this, field data (Murphy et al. 2016b) collected on a population of *U.*
177 *pinnatifida* in Brest, France, was used to create an age to mortality curve (Weibull distribution)
178 which determines the probability of premature death as a function of the age of the sporophyte.

179 In earlier versions of the model, there was a single age to mortality curve used to describe
 180 the probability of premature death among recruits. However, in the latest version, it has been
 181 updated to take into account seasonal variation in the probability of mortality (due to changes in
 182 competition). For example, in July and August there is a peak in the mortality of young recruits (<1
 183 months old), which was not taken into account in the previous version.

184 Therefore, a series of 12 individual Weibull functions (for each month of the year) were
 185 fitted to the mortality data in order to capture the seasonal variation in the probability of premature
 186 death. Cosine curves were used to describe the change in the shape (k) and scale (λ) parameters of
 187 the Weibull curve as a function of the day of the year:

$$y = A \cos[\omega(x - \alpha)] + C \quad (4)$$

188 where x is the day of the year, A is the amplitude, α is the horizontal phase shift, C is the
 189 vertical offset and ω is the angular frequency ($2\pi/365$). This functional relationship could then be
 190 used in the model to generate a probability of premature mortality based on the time of the year
 191 and the age of the sporophyte, rather than assuming a constant probability.

192

193 2.4. Validation versus field data from Brest harbour, France

194 The updated version of the model was first validated against field data collected from a
 195 population of *U. pinnatifida* growing in Brest harbour, France. The field experiment and raw data are
 196 summarized in (Murphy et al. 2016b). This consisted of monthly abundance and recruitment data for
 197 the species recorded at Brest harbour, France. Temperature data for the site were sourced from a
 198 SOMLIT (Service d'Observation en Milieu Littoral) buoy (INSU-CNRS 2015). Global solar irradiance
 199 data (in order to calculate the light availability at the sea surface) were obtained using the CALSOL
 200 online application (Institut National de L'Energie Solaire, CEA-CNRS) (INES 2015). Finally, day length

201 was calculated based on sunrise/sunset records from the U. S. Naval Observatory's Astronomical
202 Applications Department (USNO 2015).

203

204 *2.5. Predicted temperature range of U. pinnatifida*

205 In order to explore the role of temperature limitations on the potential expansion of *U.*
206 *pinnatifida* in Europe, a series of simulations to predict the relationship between mean water
207 temperature and annual population growth were carried out. The annual population growth rate is
208 defined as the change in the (log) total annual recruitment per year. In this case, factors such as
209 competition and space or nutrient limitation were ignored in order to focus on the impact of
210 temperature. A series of simulations (>150) were carried out to predict how the population growth
211 rate changes over a range of temperatures (7.5-23°C) and different amplitudes in the seasonal
212 variation of the temperature (1-8°C). This data was used to calculate the temperature ranges for
213 survival of the species, i.e. where the population growth rate is predicted to be greater than zero.

214

215 *2.6. Case studies: Effect of environmental conditions on life cycle schedule*

216 Following the high level analysis, a number of case study simulations were carried out to
217 explore the effects of environmental conditions on the life cycle schedule of the species. Three test
218 case scenarios ("North", "Central", and "South") were proposed that represent a range of
219 environmental conditions to which populations may be exposed along a latitudinal gradient in
220 Europe. These test cases are characterised by differences in the temperature, irradiance and day
221 length regimes. All other parameters are maintained constant (e.g. biotic parameters of the algae,
222 and other factors such as depth, light attenuation factor etc.). See Table 1 for a comparison of the
223 environmental input parameters that were varied between the three test case scenarios.

224 The first scenario (referred to as “North”) involved environmental parameters
225 representative of the northern edge of *U. pinnatifida*’s current reported range in Europe (Northern
226 Ireland). This test case is characterised by a relatively low mean water temperature (11.2°C) and light
227 availability (9.1 MJ m⁻² day⁻¹), as well as strong seasonal variation in day length due to the latitudinal
228 location (54.6°N). An alternative scenario, representative of the southern range limits of *U.*
229 *pinnatifida*, was also analysed (referred to as “South”). This represents conditions of relatively high
230 water temperature (19.8°C), high light availability (15.1 MJ m⁻² day⁻¹) and lower seasonal variation in
231 day length (latitude = 42.5°N). These latter conditions are similar to those present towards the
232 southern limit of *U. pinnatifida*’s current range in Europe (Ionian Sea, southern Italy) (Cecere et al.
233 2000). As a control, the results from the simulation of Brest harbour are included, referred to as
234 “Central” since it is approximately in the middle of the species’ current range distribution in Europe
235 along the North-South gradient. Brittany is also representative of the biogeographic transition
236 between Lusitanian and Boreal Province in the NE Atlantic (Spalding et al. 2007). This test case
237 represents an intermediate scenario in terms of water temperature (13.3°C), light availability (11.4
238 MJ m⁻² day⁻¹) and day length (latitude = 48.4°N).

239

240 3. Results

241 3.1. Validation versus field data from Brest harbour, France

242 The predicted relative monthly abundance and recruitment data for sporophytes of *U.*
243 *pinnatifida* were compared to field data from Brest harbour, France (Fig. 1). In terms of both relative
244 abundance (total number of sporophytes) and recruitment (number of newly recruited sporophytes,
245 >5 cm in length) the model matches closely the patterns observed in the real life population ($R^2=0.98$
246 respectively). It also shows good quantitative agreement with field data in terms of age to maturity
247 (1.6±0.1 vs. 1.9±0.5 months, mean±SE) and months mature (1.5±0.1 vs. 1.45±0.4 months, mean±SE)
248 (Fig. 2a).

249 The results of validating the model versus field data show a substantial improvement in the
250 accuracy of predictions compared to the previously published version of the model: R^2 values
251 increased from 0.84 to 0.98 and 0.85 to 0.98 for abundance and recruitment respectively (Murphy et
252 al. 2016a). This result suggests that the majority (84%) of monthly variation in abundance of *U.*
253 *pinnatifida* sporophytes can be explained by seasonal changes in environmental parameters (light,
254 temperature and photoperiodic effect). However, increased juvenile mortality in the summer could
255 be due to competitive interactions and community effects potentially offsetting the effects of high
256 recruitment.

257

258 3.2. Predicted temperature range of *U. pinnatifida*

259 Globally, *U. pinnatifida* has been found in areas with mean water temperatures (seasonal
260 range between min and max included in brackets) as low as 9.5°C (6.0 – 13.0 °C, in Southern
261 Patagonia, Argentina, Lat. -47.75 Long. -65.92) and as high as 22.4°C (16.8 - 28.0 °C, in its native
262 range of Japan, Lat. 31.85 Long. 130.15) (Dellatorre et al. 2014; Martin, Cuevas 2006; Saito 1975).
263 When simulations were carried out with seasonal temperature conditions representative of these
264 regions (amplitude = 3.5°C in Southern Patagonia, and 5.5°C in southern Japan), the model predicted
265 temperature limits for growth were 9.1°C (5.6 – 12.6 °C) and 22.5°C (17 - 28 °C) respectively, which
266 closely matches the actual range limits (9.5 & 22.4°C) above (Fig 4a). In addition to the mean annual
267 water temperature, the effect of the amplitude of the seasonal change in water temperature
268 (between the warmest and coolest months of the year) was explored in more depth. The results
269 indicate that the theoretical thermal niche of *U. pinnatifida* increases as a function of the amplitude
270 of the seasonal change in temperature (Fig. 3b).

271

272 3.3. Case studies: Effect of environmental conditions on life cycle schedule

273 There are clear differences in the seasonal patterns of abundance and recruitment between
274 the three case study populations (Fig. 4). For example, the northern population is predicted to peak
275 in abundance later in the year (April) compared to the southern population (March) (Fig 5a), and has
276 lower overall recruitment compared to both the central and southern populations (Fig 5b). There are
277 also distinct differences in the seasonal growth rates of the individual sporophyte and gametophyte
278 agents (Fig. 5). In general, the populations further south are predicted to reach optimal growth rates
279 earlier in the spring, before temperature becomes a limiting factor. Furthermore, individuals in the
280 south have a shorter predicted lifespan since they reach maturity and release their spores earlier in
281 the year (Fig. 2b) due to spore release triggered by warming temperatures (Suto 1952).

282 Finally, the effect of environmental conditions on gametophyte fertility (and thus the
283 formation of a new generation of sporophytes) was compared across the three locations (Fig. 6). For
284 the central and northern populations, there are two clear annual peaks in the fertility of
285 gametophytes, in October and February respectively. However, the southern population lacks the
286 autumn peak due to inhibition of gametogenesis and therefore has a narrower window of
287 opportunity for forming a new generation of sporophytes. This also explains the characteristic
288 pattern of recruitment observed in Figure 4b where the southern population lacked a secondary
289 minor peak in recruitment in late November.

290

291 **4. Discussion**

292 The close agreement between the predicted abundance and recruitment values with field
293 data for sporophytes growing in Brittany, France (Fig. 1) is particularly interesting in light of the
294 diverse sources of input data used to parameterise the model. For the most part, the
295 ecophysiological data used to parameterise the model came from individuals sampled in the study
296 species' native range of eastern Asia (due to a lack of equivalent information for European

297 populations). For example, the temperature response curves for the gametophytes and sporophytes
298 came from individuals sampled in Japan (Morita et al. 2003a, b). Similarly, the effects of light and
299 day length on gametophyte growth and reproduction were based on studies in the Korean peninsula
300 (Choi et al. 2005). Finally, photosynthesis-irradiance curves for the sporophytes were sourced from
301 studies in south-eastern Australia (Campbell et al. 1999).

302 Therefore, it is noteworthy that the model predicts a pattern of monthly recruitment and
303 abundance that closely matches the patterns observed among a population growing in western
304 France ($R^2=0.98$). This suggests potentially strong phenotypic conservation in terms of its response
305 to environmental factors since the species' introduction to Brittany, France over 40 years ago. This
306 may be explained by a large physiological niche for *U. pinnatifida*. Broad physiological tolerance is an
307 important component of invasiveness in terrestrial plants (Higgins, Richardson 2014). But there are
308 currently no similar studies available for macroalgae, and a lack of experimental data on the basic
309 physiological responses of *U. pinnatifida* populations in Europe compared to those in its native
310 range.

311 Similarly, the model predicted temperature limits match closely with the current known
312 global distribution for *U. pinnatifida* when taking into account both the mean water temperature
313 and the amplitude of seasonal variation (Fig. 3a). In particular, the size of the species' ecological
314 niche is shown to be directly related to the amplitude in seasonal variation of temperature (Fig. 3b).
315 This demonstrates that *U. pinnatifida* has a wider ecological niche in conditions of high seasonality,
316 and is consistent with theories that propose the heteromorphic life cycle, characteristic of species
317 such as this, may have evolved as an optimal growth strategy for highly seasonal environments
318 (Bessho, Iwasa 2009).

319 However, there are a number of other indirect effects which must be taken into account
320 when determining the theoretical range limits of *U. pinnatifida*, for example how changes in the
321 seasonal pattern and timing of recruitment might affect its competitive ability versus native species.

322 These changes can affect its ability to invade natural habitats, even when the temperature
323 conditions are suitable for recruitment. For example, James et al. (2015) discussed how seasonal
324 changes to phenology may affect impacts from invasion. To explore this, a number of test cases
325 scenarios were designed to represent the conditions populations are exposed to at the current
326 northern and southern range limits of *U. pinnatifida* in Europe.

327 The differences in growth and recruitment patterns (Fig. 4) can be explained by changes in
328 the fundamental growth rates of the *U. pinnatifida* agents in response to the environmental
329 parameters. The predicted growth rates of both the gametophyte and sporophyte stages of the life
330 cycle are limited by sub-optimal temperature and irradiance conditions in the north (Fig. 5). There is
331 also a delay in the shedding of spores due to inhibition under cooler water conditions in early
332 summer which may explain the delayed pattern of recruitment in the northern population (<12°C)
333 (Suto 1952). However, there is another notable feature in the predicted recruitment, for both the
334 Central and Northern populations, evident in Figure 4b. That is the presence of a minor secondary
335 recruitment peak in November, in addition to the primary spring peak in April. This secondary annual
336 peak in recruitment is absent from the predicted results for the southern population.

337 This secondary peak of recruitment has been observed in the field data from the population
338 surveyed in Brest harbour (Fig. 1b) and in populations introduced in other temperate regions where
339 temperatures vary annually between 10 and 21°C (N America; Thornber et al. 2004). This pattern of
340 recruitment can be explained by differences in the seasonal patterns of gametogenesis (Fig. 6). The
341 model predicts a delay of several months in the onset of maturity among *U. pinnatifida*
342 gametophytes on the southern range edge. This results in a substantial change in the seasonal
343 pattern of gametogenesis that, if exhibited in natural populations, could significantly impact their life
344 cycle schedule and affect their potential for establishment in lower latitudes. *U. pinnatifida* is
345 considered an opportunistic and pioneering species and the ability to recruit earlier in the year is
346 thought to confer on it a competitive advantage compared to native macroalgal species in Brittany,

347 France (Grulois et al. 2011). However, in the Mediterranean Sea, a delay in gametogenesis could play
348 a critical role in limiting the ability of *U. pinnatifida* to supplant native species from their ecological
349 niche.

350 Indeed, although the first reported occurrence of *U. pinnatifida* in Europe occurred in Étang
351 de Thau, on the Mediterranean coast of France in the 1970's, it has failed to establish itself in the
352 surrounding region subsequently (Floc'h et al. 1991). It is still present in Thau lagoon but only in a
353 small number of discrete locations and it has not expanded outside the lagoon (F. Viard, pers. obs.).
354 Potential explanations for this have included nutrient limitations due to the oligotrophic nature of
355 this region of the Mediterranean Sea (Báez et al. 2010). Indeed, populations have been found in
356 nutrient-rich polluted waters in the Venice lagoon and the Ionian Sea off southern Italy (Cecere et al.
357 2000; Curiel et al. 1998; Curiel et al. 2002). Other factors such as chlorophyll concentration and
358 shading have also been shown to be important for the growth of the species (Báez et al. 2010).

359 The results in the current study represent a potential alternative explanation, for the lack of
360 expansion in Mediterranean populations, through disturbance to the life cycle schedule of the
361 species. A delay of a few months in the predicted onset of gametogenesis under the warmer
362 southern conditions could be a critical factor in reducing the population's ability to settle and
363 establish itself opportunistically in the natural habitat. This also agrees with theoretical studies that
364 have indicated macroalgal species with heteromorphic life cycles, such as *U. pinnatifida*, may be
365 better adapted to the more strongly seasonal environments of northern latitudes (Bessho, Iwasa
366 2009). This could limit the species competitive ability to establish itself in lower latitudes even in
367 cases where nutrient limitation is not a factor.

368 With regard to the northern range limits of *U. pinnatifida* in Europe, currently the most
369 northerly reported population is in Northern Ireland where mean annual water temperatures are
370 approximately 11-12°C (Minchin, Nunn 2014). This is within the tolerance limit for the sustainability
371 of a population according to the model predictions (Fig. 3). This also agrees with other studies, using

372 habitat suitability models, which have indicated that temperature may not be a limiting factor for its
373 distribution in the British Isles (Yesson et al. 2015). In terms of gametogenesis, populations are also
374 predicted to maintain the characteristic bi-annual peak in gametophyte fertility (Fig. 5). This means
375 that it also has the potential to be an opportunistic invader through early recruitment.

376 Therefore, under this model, the environmental conditions are predicted to be suitable for
377 the continued spread of the species as an invasive threat in the British Isles, particularly under
378 scenarios of increasing sea water temperatures (Mackenzie, Schiedek 2007). However, expansion to
379 waters with a mean annual temperature $<10^{\circ}\text{C}$ will depend on the seasonal variation in the
380 temperature. When the seasonal amplitude in water temperature is $<3.5^{\circ}\text{C}$, then the minimum
381 temperature a population is predicted to survive in is $>9.1^{\circ}\text{C}$ (Fig. 3a). However, in the case of a high
382 variation between summer and winter temperatures (amplitude 5.5°C), it is possible that
383 populations of *U. pinnatifida* could survive in conditions where the mean annual temperature is as
384 low as 8°C . In this case, other factors such as light or nutrient availability might become more
385 important limiting factors.

386 These model results indicate that both direct and indirect effects on the life cycle schedule
387 may determine the future expansion potential of *U. pinnatifida* in Europe and elsewhere. These
388 types of subtle interactions are not as readily apparent when considering the invasion from a
389 population perspective only. This modelling approach represents a promising framework that could
390 be applied to other species of macroalgae with heteromorphic life histories in order to understand
391 better their growth and life cycle dynamics and how these contribute to their potential distribution
392 range under variable climatic conditions.

393 Future work will require a detailed analysis of the role of other factors such as nutrient
394 limitations and biotic interactions versus direct and indirect effects of environmental factors on the
395 life cycle schedule of *U. pinnatifida* in order to build a complete picture of the invasion dynamics.
396 This model is somewhat limited in that it focuses on seasonal changes in light, temperature and day

397 length only. Nevertheless, the results raise interesting points about the role of changes in the life
398 cycle schedule and seasonal cycle on the invasive potential of species such as *U. pinnatifida*.
399 Potential temporal changes in the life cycle schedule of introduced species outside their native range
400 can have important impacts when it comes to accurately predicting their range limits and should be
401 considered in future modelling studies.
