17 Highlights:

- 18 • Archeointensity analysis performed on Early Byzantine ceramics unearthed in Greece
19 • 5 new high quality archeointensity data obtained using the Triaxe protocol
20 • Geomagnetic field intensity increase observed in the Balkans from 4th to 7th C.

21
22 Keywords:

23 Archeomagnetism; Archeointensity; Secular variation; Greece; Early Byzantine period;
24 Pottery

26 **Abstract**

27 We report on five new archeomagnetic field intensity data obtained in Greece from groups of
28 pottery fragments precisely dated to between the middle of the fourth century and the
29 beginning of the seventh century CE. These potsherds were unearthed on the islands of
30 Thasos (Northern Greece) and Delphi (Central Greece). Their dating is primarily ensured by
31 typo-morphological arguments, combined with archeological and historical constraints.
32 Archeointensity measurements were performed using the Triaxe protocol, which involves
33 continuous magnetization measurements at high temperatures and which allows us to
34 overcome the thermoremanent magnetization anisotropy and cooling rate effects. Magnetic
35 mineralogy measurements such as low-field magnetic susceptibility versus temperature and
36 thermal demagnetization of three orthogonal IRM components have identified magnetite with
37 possible impurities as the main carrier of the magnetization. The new data range from $52.0\mu\text{T}$
38 to $61.5\mu\text{T}$ after reduction to Thessaloniki and show an increase in geomagnetic field intensity
39 in Greece during the Early Byzantine period. They appear in good agreement with previous
40 intensity results satisfying a set of quality criteria and obtained in a region of 700 km around
41 Thessaloniki, therefore incorporating data from Bulgaria, Greece and South Italy. This study
42 is part of an ongoing effort to better constrain the evolution in geomagnetic field intensity in
43 the Balkans over the past few millennia, with potential use for dating in archeology. The rapid
44 intensity variations documented here during the Early Byzantine period are clearly of interest
45 in this respect.

46

47 **1 Introduction**

48 Archeomagnetic data constitute a valuable source of information on the Earth's
49 magnetic field variations during the last few millennia. Data compilations from all over
50 Europe, where the discipline has flourished over the last few decades, have resulted in the

51 construction of robust databases and the computation of secular variation curves for several
52 regions including France (Gallet et al., 2002; Hervé et al. 2013a,b; Genevey et al., 2016),
53 Germany (Schnepp and Lanos, 2005), Italy (Tema et al., 2006, 2013) and the UK (Zananiri et
54 al., 2007) among others. There are, however, usually more directional than intensity data
55 available, a feature related to the time-consuming and complicated protocols required to
56 determine the archeointensity, together with the frequently high rate of failure.

57 Numerous archeomagnetic investigations conducted within the last forty years in the
58 Balkans have resulted in a particularly well-documented secular variation of the Earth's
59 magnetic field, with a complete, though not continuous, recovery of the geomagnetic behavior
60 (i.e. both in direction and in intensity) over the past eight millennia. This largely relies on
61 datasets obtained in Bulgaria, where the compilation of archeomagnetic results has recently
62 been updated (Kovacheva et al., 2014), and includes full vector data, obtained exclusively
63 from in-situ burnt structures.

64 Archeomagnetic studies were initiated in Greece, in the 80's (Thomas, 1981; Walton,
65 1984; Aitken et al., 1989) and in contrast to the general overview in Europe, there is more
66 archeointensity than directional data. Nevertheless, the quality of several Greek
67 archeointensity data has often been criticized (for a review see De Marco et al., 2008a) while
68 several newly acquired results (Spatharas et al., 2011; Tema et al., 2012; Fanjat et al., 2013;
69 De Marco et al., 2014) have supplemented the database with reliable input. As a result, the
70 main trends of the geomagnetic field secular variation in the Balkans can now be used for the
71 dating of baked clay structures of uncertain age. Several examples exist in the literature where
72 archeomagnetic dating results are successfully compared with thermoluminescence or
73 radiocarbon data and archeological constraints (Aidona and Kondopoulou, 2012; Tema et al.,
74 2015; Kondopoulou et al., 2015).

75 In spite of its great potential, the precision of archeomagnetic dating in the Balkans is
76 still limited by the dispersion seen in the data, which suggests that some of the published
77 results are biased and/or their uncertainties underestimated (e.g. Pavón-Carrasco et al., 2014).
78 As a consequence, the detailed recovery of the geomagnetic fluctuations in this region,
79 although an achievable target given the richness of its archeological and historical heritage,
80 still requires the acquisition of new, high-quality, data with a precise control of age. The
81 present study is part of this effort.

82 We report on five new archeointensity data obtained from groups of ceramics
83 unearthed in Greece on the islands of Thasos and Delphi, two historical excavation sites of the
84 French School at Athens (Péntazos and Picard, 1992; Jacquemin, 2000; Mulliez, 2011; Muller
85 and Mulliez, 2012). These ceramics are precisely dated to the Early Byzantine period,
86 between the 4th and the 7th centuries CE. We will see that this time interval proves to be
87 particularly interesting for both geomagnetic and archeological dating purposes as it was
88 characterized by significant and rapid geomagnetic field intensity fluctuations.

89

90 **2 Archeological collection**

91 Our archeological collection is composed of six groups of ceramic fragments, three of
92 them collected at Thasos (40.7°N, 24.6°E) and the other three at Delphi (38.5°N, 22.5°E; Fig.
93 1a). We underline that these groups were selected among the large amount of ceramic
94 material unearthed from these two major archeological sites. The accuracy and reliability of
95 the dating (an uncertainty of 100 years was fixed as a limit) and the precise knowledge of the
96 location of the ceramic production site were a pre-requisite for our sampling in addition to
97 considerations regarding the clay paste and the atmosphere of heating/cooling.

98 At Thasos, a joint project of the French School at Athens (represented by the
99 University of Lille - UMR Halma - and the National and Kapodistrian University of Athens)

100 and the Greek Ministry of Culture (represented by the Ephorate of antiquities of Kavala-
101 Thasos) has brought to light a Late Roman/Early Byzantine urban villa called *DOM5* (for the
102 latest excavation report see Blondé et al., 2014). This villa was built at the end of the 4th/
103 beginning of the 5th century CE and was destroyed no later than 619/620 CE. This date is
104 attested to by numerous coins dated to 619 CE found in the destruction layers of the villa,
105 whereas no later coins have been discovered. From the 5th century to its abandonment, the
106 status of the villa had evolved from a luxurious *domus*, with the construction of private baths
107 during the 5th or 6th century, to a more modest use after ca. 570 CE that saw a rearrangement
108 of the house.

109 The three studied groups of pottery fragments were discovered in various occupation
110 or dump layers of the villa. Each group is not associated to a single stratigraphic unit or
111 context but in fact comes from different parts of the villa. The temporal homogeneity and the
112 dating of the groups are, however, ensured by the typo-morphology of the fragments. Two of
113 them belong to well-known and broadly distributed types of a famous Asia Minor production
114 of Late Roman *Terra Sigillata* or *Phocaean Red Slip* ware (LI03 and LI04 groups, Fig. 1b;
115 Hayes, 1972, LRC ware) with, for each group, one well-known shape selected (Table 1). The
116 typo-chronology for the LRC ware was derived from the identification and classification of
117 ten specific forms (and their variants) of this production and from their discovery in a number
118 of archeological locations of the Eastern Mediterranean, which provided closed and well-
119 dated (particularly from coins) contexts (Hayes, 1972, 1980). This type of production was
120 widely distributed in the Eastern Mediterranean region from the 4th to the 7th century CE and
121 its provenance was identified at the region of Phocaea (38.7°N, 26.8°E) in Asia Minor (for the
122 workshops see Hayes, 1980; Empereur and Picon, 1986; Mayet and Picon, 1986). We
123 underline that its recognition on archeological sites is largely used as a dating marker together
124 with other imported fine wares such as the African Red Slip Ware (Hayes, 1972; Bonifay,

125 2004) or Late Roman D Ware (Hayes, 1972). We note that group LI03 includes also a few
126 potsherds retrieved from the southern sector of the *Agora* of Thasos, identified as the
127 *Macellum* (Marc, 2008; Excavations carried out by the French School at Athens). These
128 fragments display the characteristic shape of the LI03 group, i.e. the 3C form dated to the
129 second half of the 5th century.

130 The third group from Thasos is composed of potsherds identified as *Central Greek*
131 *Painted Ware* (LI05 group; Hayes, 1972; Pétridis, 1997, 2009). The classification and dating
132 of this production rely also on cross-data obtained on different archeological dated contexts
133 from consumption sites among which we may cite Argos, Athens, Delphi, Thessaloniki or
134 even more distant sites such as Abu Mena in Egypt and Constantinople. Its production site
135 was identified at Nea Anchialos (39.3°N, 22.8°E) in Thessaly (Fig.1a, Pétridis, 1997, 2009)

136 Late Roman/Early Byzantine remains were unearthed at Delphi as early as the end of
137 the 19th century but they had not received the attention they deserved (Pétridis, 1997). The
138 restarting of excavations of Late Roman/Early Byzantine layers at Delphi in the 1990's by the
139 French School at Athens allowed the uncovering of two artisanal districts with evidence of
140 pottery activity. The first, dated to the second half of the 4th century is located close to the
141 *Gymnasium* of ancient Delphi, while the second, that was precisely dated by coins and
142 imported pottery between 590 and 620 CE, is located South East of the *Peribolos*, in a place
143 once occupied by the so-called *South-Eastern Villa* (Déroche et al., 2014). These excavations
144 revealed a ceramic production of good quality, with a large corpus of shapes, covering the
145 needs of a local and regional clientele (Pétridis, 2010). The two younger groups, referred to as
146 DEL01 and DEL02, are associated with the *South-Eastern Villa* area. They were found in
147 pottery deposits located close to the kilns and were identified as ceramic wasters (Fig. 1c).
148 The dating interval is first constrained by stratigraphical arguments. The workshop indeed
149 settled over a villa whose abandonment as a habitation unit is dated at about 580 CE by coins

150 and imported ceramics. A *half follis* of Maurice struck in 588/589 CE, which was discovered
151 in one of the structures of the workshop further helps to date the beginning of its activity. This
152 activity stopped some thirty years later as evidenced by coins all dated before 620 CE and
153 imported vessels (in particular by African Red Slip Wares), none of which can be dated to
154 after 620 CE. Finally, the dating also relies on the hypothesis of the capacity and lifetime of
155 the deposit (Pétridis, 2010). We note that the two groups were named differently to
156 distinguish between fragments of pottery bases and fragments of pottery lips. They however
157 come from exactly the same context and share the same age. Therefore their intensity results
158 will be discussed together.

159 The last group from Delphi (DEL03) is from a large ensemble of ceramic fragments
160 discovered in a shop, possibly a workshop, in the North-Eastern corner of the *Roman Agora*.
161 The fragments were in fact used to fill-in the space after its partial destruction, probably due
162 to the earthquake of July 21, 365 CE (Petridis, 2010). This devastating seism was described
163 by the historian Ammianus Marcellinus (330-395) in his *Res gestae* and was felt throughout
164 the eastern Mediterranean region (Guidoboni et al., 1994). The dating of the DEL03 ensemble
165 is constrained by imported *terra sigillata* wares and reinforced by the study of the coins found
166 in this context (most of them belonging to the Constantinian dynasty). All the fragments
167 examined belong to the local production, which has already been an object of both a chemical
168 and a petrographic analysis (see Kouzéli in Pétridis, 2010). We note that these combined
169 experiments of XRF, XRD, and thin section observations allowed the distinction of two clay-
170 paste groups with as a common feature their high content in iron oxides (Fe_2O_3) with a
171 percentage of 7.90%.

172

173

174

175 **3 Archeointensity measurements**

176 Our analyses aim at recovering the intensity of the ancient geomagnetic field recorded
177 by ceramics during their manufacture, more precisely during their cooling in the kilns. This
178 information is recorded through the acquisition of a Thermo-Remanent Magnetization (TRM)
179 whose direction is parallel to that of the ambient Earth's magnetic field and whose moment is
180 proportional to its intensity. When ceramics are removed from the kiln, the information on the
181 geomagnetic direction is lost, while that of the intensity is retained and may be retrieved.

182 The main principle of the archeointensity measurements is to replace the Natural
183 Remanent Magnetization (NRM) recorded by the fragments by a new TRM acquired in
184 known field conditions (direction and intensity). In this study the archeological artifacts were
185 analyzed using a tailored experimental protocol designed for the Triaxe magnetometer (Le
186 Goff and Gallet, 2004). The Triaxe protocol derives from the method of Thellier and Thellier
187 (1959). Its originality relies on the fact that the magnetization measurements are performed
188 continuously at high temperatures. This protocol was described in detail in previous
189 publications (e.g. Le Goff and Gallet, 2004, Gallet and Le Goff, 2006; Gallet et al., 2014) and
190 only a concise overview is given below.

191 The entire sequence of measurements is achieved within a little more than 2 hours and
192 is performed on one specimen of 1 cm in length and with a thickness/diameter depending on
193 the shape of the potsherd. It involves 4 successive steps:

- 194 • Step 1: Almost complete demagnetization of the NRM up to a high temperature
195 referred to as T2, here comprised between 450 °C and 530 °C depending on the
196 fragments.
- 197 • Step 2: The specimen is cooled to a low temperature referred to as T1 (set to 150 °C)
198 and again heated to T2 in order to measure the temperature dependence of the
199 spontaneous magnetization of the small fraction of the NRM remaining above T2.

200 • Step 3: Acquisition of a TRM by cooling the specimen from T2 to T1. Its direction is
201 precisely set parallel to that of the NRM. The intensity of the applied field is also
202 chosen to be close to the expected one.

203 • Step 4: Demagnetization of the newly acquired laboratory TRM between T1 and T2.

204 For each temperature T_i running from T1 to T2 by steps of ~ 5 °C, the $R'(T_i)$
205 parameter is computed (Le Goff and Gallet, 2004). This parameter is given by the ratio
206 between the NRM and TRM fractions demagnetized between T1 and T_i multiplied by the
207 intensity of the laboratory field. A mean intensity value is finally estimated at the specimen
208 level from the averaging of all $R'(T_i)$ values. When a secondary magnetization component
209 partly overprints the original TRM, the $R'(T_i)$ values are then computed between a higher
210 temperature T_1' and T2, i.e. the temperature range where the original TRM is reliably
211 isolated.

212 In the Triaxe protocol, it is worth stressing that the laboratory field is applied so that
213 the direction of the new TRM is parallel to that of the NRM. This allows us to overcome the
214 TRM anisotropy effect, which originates from the stretching of the clay during the
215 manufacture of the object (e.g. Aitken et al., 1981). Furthermore, it has been experimentally
216 and repeatedly observed on archeological artifacts of different types and origins that the
217 intensity data obtained using the $R'(T_i)$ parameters took into account the cooling rate effect
218 (Le Goff et Gallet, 2004; Genevey et al., 2009; Hartmann et al., 2010; Genevey et al., 2016).
219 We briefly recall that this effect is related to the dependence of the TRM acquisition on the
220 cooling rate (e.g. Fox and Aitken, 1980) and to the fact that there is generally a large
221 difference between the original cooling rate, during which the original TRM/NRM is recorded
222 in the kiln and the cooling rate applied for the laboratory TRM acquisition (e.g. Genevey et
223 al., 2008).

224

225 **4 Rock magnetism investigations**

226 Possible alteration due to heating was first investigated through susceptibility
227 measurements performed from 50 °C up to ~500-525 °C, i.e. on the temperature range used
228 for intensity determinations. Only pottery fragments showing reversible heating and cooling
229 susceptibility curves were retained for further analyses (Fig. 2a,b,c,d). For these selected
230 fragments, a second series of susceptibility measurements were carried out up to ~680 °C. For
231 the *Terra Sigillata* produced at Phocaea (LI03 and LI05) and for the *Central Greek Painted*
232 *Ware* production (LI04), the heating at higher temperature induced a strong alteration of the
233 magnetic mineralogy, with higher susceptibilities observed on the cooling curves, most
234 probably originating from the formation of new magnetite (Fig. 2f,g). These results highlight
235 the advantage of investigating the magnetic mineral stability on the same temperature range
236 as the one used for the intensity determinations rather than on a wider temperature interval. In
237 the latter case, this would have led to the rejection of these three groups of pottery fragments.
238 In contrast, the ceramics from Delphi appear more stable upon heating (Fig. 2e,h). Whatever
239 the production, the heating susceptibility curves usually exhibit two inflexion points, at low
240 (200-300 °C) and medium-high temperatures (450-550 °C).

241 The magnetic mineralogy of this collection was further investigated through the
242 thermal demagnetization of three-axis Isothermal Remanent Magnetization (2 T, 0.4 T, and
243 0.2 T) acquired in three perpendicular directions (Lowrie, 1990). These experiments were
244 carried on two to four fragments per group among those that provided reliable intensity
245 results. In most fragments, they show the predominance of a magnetic phase, likely from the
246 magnetite family (with possible impurities), of low coercivity (<0.2 T) and with unblocking
247 temperatures below 550 °C (Fig. 3). Another phase characterized by low unblocking
248 temperatures (200-250 °C) and high coercivity is also systematically observed, but in various
249 proportions (Fig. 3). The very same phase has been widely documented in archeomagnetic

250 studies, while its clear identification remains an open question (McIntosh et al., 2007, 2011).
251 Finally, a small fraction of hematite is also observed, which, we note, was not detected from
252 the susceptibility measurements (Figs. 2,3). In summary, the magnetic mineralogy hence
253 appears as a combination of magnetite (in majority), a mineral of low-unblocking
254 temperatures (200-250°C) and high coercivity (>2T), and a small fraction of hematite. Such a
255 combination is in fact rather common in baked clay archeological artifacts (e.g. Hartmann et
256 al., 2010; Genevey et al., 2016).

257

258 **5 Intensity Results**

259 In addition to the required stability of the magnetic mineralogy constrained by
260 susceptibility measurements, a set of selection criteria was applied on the archeointensity data
261 in order to only retain the most reliable results. These criteria are the same as those used in
262 our previous investigations using the Triaxe protocol (e.g. Genevey et al., 2009, 2013;
263 Hartmann et al., 2011; Gallet et al., 2014). These criteria aim to test the quality of the
264 intensity determinations at the specimen level, with analyses strictly performed on the same
265 temperature range where the primary TRM was reliably isolated. Over this temperature
266 interval, the slope of the $R'(T_i)$ values must be of less than 10% and must concern more than
267 50% of the magnetization fraction with an unblocking temperature larger than T_1 (or T_1' , K%
268 parameter; Supplementary Table S1; Gallet et Le Goff 2006). At the fragment level, two to
269 three specimens were analyzed and the results must agree to within 5%. Finally, at least three
270 fragments are required to define a mean value at the group level and its standard deviation
271 must be of less than 10% and $5 \mu\text{T}$.

272 A total of 63 specimens from 23 fragments were successfully analyzed and used to
273 derive five new archeointensity values encompassing the Early Byzantine period in Greece
274 (Table 1 and supplementary Table S1). All retained intensity determinations were reported at

275 the specimen level in Fig. 4, with one panel per group. For each group, an example of thermal
276 demagnetization is also presented in Fig. 4. These diagrams illustrate the different behaviors
277 observed; that is, for part of the fragments, two components of magnetization observed above
278 150°C (Fig. 4b,f,j) and an intensity determination performed on the temperature range where
279 the primary component was isolated (Fig. 4a,e,i). The thermal demagnetization of the other
280 fragments revealed only one component of magnetization above 150 °C (Fig. 4d,h) and the
281 intensity determination therefore concerned the entire temperature range above T1 (Fig. 4c,g).
282 The percentage of success is relatively low, between 33% and 50%, on the understanding that
283 this percentage relates to the number of fragments whose magnetic moment was strong
284 enough to be measured on the Triaxe (supplementary Table S1). For these fragments, the
285 main causes of rejection were either related to their unstable magnetic mineralogy upon
286 heating, or because the slope of the R'(Ti) values was too strong over the temperature range
287 where the TRM was isolated, or because it was not possible to reliably isolate this primary
288 magnetization component (i.e. the magnetization acquired during the manufacturing of the
289 artifacts).

290 The five new intensity results are reported in Fig. 5, together with a selection of
291 intensity results available inside a region of 700 km around Thessaloniki (see below). These
292 new data are well defined with standard deviations between 1% and 5% of the corresponding
293 means, the latter ranging from 52.0 μ T to 61.5 μ T after reduction to Thessaloniki (Table 1).
294 They clearly show an increase of the geomagnetic field intensities in the Balkans between the
295 middle of the 4th century and the beginning of the 7th century CE.

296

297 **6 Discussion**

298 Archeomagnetism has largely been developed in the Balkan Peninsula, in particular
299 through the numerous archeomagnetic studies carried out in Bulgaria since the late seventies

300 (Kovacheva et al., 2014 and references therein) and with the development of this discipline in
301 Greece over the past fifteen years (Spatharas et al., 2000; De Marco et al, 2008a,b; Aidona
302 and Kondopoulou, 2012; De Marco et al., 2014 among others). Regarding intensity, the
303 available dataset allows a description of the geomagnetic variations over nearly the past eight
304 millennia, making it, together with the one from the Middle East (Gallet et al., 2015), one of
305 the longest archeomagnetic records.

306 The Balkan archeointensity dataset for the past three millennia was evaluated by
307 Pavón-Carrasco et al. (2014), who underlined the rather small percentage of results satisfying
308 modern quality criteria (see also the discussion in Tema and Kondopoulou, 2011). Taking
309 advantage of the recent update of the Bulgarian archeomagnetic database (Kovacheva et al.,
310 2014), we explore here again the Balkan results available for the first millennium CE, which
311 is the period of interest of our study. The quality criteria considered below are those used in
312 our previous studies conducted in Western Europe (e.g. Genevey et al., 2016) and can be
313 summarized as follows. We only retain the data obtained using the original and derived
314 versions of the method of Thellier and Thellier (1959) or the original method of Shaw (1974).
315 The mean intensity must be defined by at least three independent values and the associated
316 error must $\leq 15\%$ of the corresponding mean. The TRM anisotropy effect must be taken into
317 account for objects generally regarded as particularly anisotropic, such as pottery and tiles.
318 The data respecting these criteria are reported in Fig. 5a. In this figure, a distinction was also
319 made between the data whose reliability was further constrained by partial-TRM checks
320 (pTRM-checks; solid symbols), allowing to better control the magnetic mineralogy stability
321 on heating of the studied fragments, and the data with no such stability test (empty symbols).

322 As a whole, Fig. 5a shows a rather large variability of the archeointensity results.
323 When the data are close in age, this scatter may, in some cases, raise questions about their
324 accuracy, either regarding their experimental determinations or their dating. This is

325 particularly the case for the data belonging to the first four centuries CE (see below).
326 However, taken as a whole, the data support the occurrence of rapid and large intensity
327 variations during the first millennium CE. For the Early Byzantine period, all results converge
328 to indicate a significant increase in intensity from the 4th century CE until about the first half
329 of the 7th century. Our new data are in good agreement with this evolution (Fig. 5a). A relative
330 minimum in intensity is then observed around the transition between the 7th and 8th century
331 CE, the intensity increasing again afterwards. It is interesting to note that a similar evolution
332 was recently documented in Western Europe (Gómez-Paccard et al., 2012, Genevey et al.,
333 2016), even though the fluctuations appear to be more intense in Eastern Europe.

334 The use of the pTRM-checks as a selection criterion has a strong impact for the time
335 interval covering the first four centuries CE (compare Fig. 5a and b). For instance, there is at
336 present no result constrained by pTRM-checks available for the period between the end of the
337 second century CE and the end of the third century CE (Fig. 5b). Using only the most reliable
338 archeointensity data obtained over Europe, Pavón-Carrasco et al. (2014) developed an
339 archeomagnetic field model which predicts for the Balkans a decrease in intensity during the
340 first three centuries followed, as previously mentioned, by an increase during the Early
341 Byzantine period (Fig. 5b). Our new result dated to the second half of the 4th century (DEL03)
342 is in good agreement with this trend, and so it is with two precisely dated results obtained in
343 southern Italy (Tema et al., 2013). We note however that a few recent data (Spatharas et al.
344 2011; Kondopoulou et al. 2015), whose dating remains poorly defined, and which were not
345 retained to derive the archeomagnetic field model A of Pavón-Carrasco et al. (2014), could
346 also support the occurrence of rapid variations during the 4th century.

347 Although our new results appear to agree with the trend in intensity fluctuations, they
348 seem to be systematically lower than the other mentioned data, in particular for the 5th and 6th
349 centuries (Fig 5b). It is noteworthy that the Bulgarian data are not corrected for the cooling

350 rate effect, which, when taken into account, usually tends to decrease the intensity values.
351 This issue was discussed in Kovacheva et al. (2014) who acknowledged that this effect might
352 indeed affect intensity values, at least for the data obtained on bricks. In Fig. 5b, the Bulgarian
353 data are reported with different symbols depending on the type of analyzed objects (i.e. with a
354 distinction between bricks, kilns, baked clays and baked soils). A cooling rate correction of a
355 5% decrease was applied on the Bulgarian data obtained from bricks, which represent the
356 majority of the dataset for the 5th and 6th centuries (Fig. 5c), the other data remaining
357 unchanged. Such a correction is a reasonable educated guess (e.g. Genevey et al., 2008),
358 although we recognize that the cooling rate effect may in fact vary from one object to another.
359 Clearly a 5% decrease of the Bulgarian intensity values would improve their agreement with
360 our new results (Fig. 5c). At this stage, however, the question of the exact cooling rate
361 correction factors required for the Bulgarian data remains unresolved and any further
362 discussion on the significance of possible shifts between different datasets would require a
363 systematic evaluation of the cooling rate effect for all data.

364 In spite of the complexity described above, we further selected the data with age
365 uncertainties of less than 100 years. This smaller dataset, that includes our five new
366 archeointensity data, was used to derive a mean archeointensity variation curve spanning the
367 first millennium using a sliding windows of 75 years shifted every 10 years (Fig. 5c). We
368 emphasize the fact that this curve, presented with its 2-s envelope, provides a likely accurate
369 picture of the present knowledge on the secular geomagnetic field intensity variations in the
370 Balkans during the first millennium CE, as constrained by using only the most reliable
371 regional data.

372

373

374

375 **7 Concluding remarks**

376 This study reports on 5 new archeointensity data obtained from Greek pottery
377 fragments precisely dated to the Early Byzantine period. These data allow to better constrain a
378 significant geomagnetic field intensity increase in the Balkans between the fourth and seventh
379 centuries CE. Such a feature appears particularly well established, even though the Balkan
380 archeointensity dataset is severely penalized by a large scatter in the available results. It is
381 worth pointing out that our study highlights the great potential of precisely dated potsherds for
382 archeomagnetism, which have been, surprisingly, rarely exploited until now in this broad
383 area.

384 Beside its implication for the regional geomagnetic field behavior, i.e. with the
385 occurrence of rapid, centennial-scale intensity variations, the Early Byzantine intensity
386 increase may also have interesting implications for archeological purposes. Archeointensity
387 analyses may indeed help in deciphering the duration of certain ceramic productions in the
388 Balkans such as the production of the Late Roman *Phocaeen Terra Sigillata*, which may have
389 persisted during the 7th century. Such issues would clearly strengthen effective collaboration
390 between archeologists and archeomagnetists.

391

392 **Acknowledgments**

393 The excavations of the French School at Athens (EfA) established at Thasos and Delphi were
394 indicated to us for their potential by Prof. D. Mulliez, Director of EfA in 2010, who included
395 our emerging project as part of the 2012-2016 five-year contract. Prof. A. Farnoux, the
396 current Director of the School has continued the support of our study, together with J.
397 Fournier, the previous Director of Studies. We address our deep acknowledgements to all.

398 The visits to the storage rooms of both Museums and the permissions to obtain the selected
399 materials for study were provided by the Ephorates of Kavala-Thasos and Fokis. It is our

400 pleasure to thank their Directors, Ms. S. Dadaki and Ms. A. Psalti respectively. We also thank
401 Dr. D. Malamidou and Dr. N. Petrocheilos for their help in accessing the material in Thasos
402 and Delphi.

403 We are grateful to Yves Gallet for his helpful comments on the manuscript, to Maxime Le
404 Goff for his support regarding the Triaxe measurements, and to Ruven Pillay for his
405 corrections to the manuscript's English. Finally we thank two anonymous reviewers for a
406 careful reading that has helped to improve the manuscript.

407 This study was partly financed by the INSU-CNRS program "PNP".

601

602 **Fig. 4.** Archeointensity determination for the different studied pottery groups and examples of
603 thermal demagnetization diagram. In the left panels, each curve represents the intensity
604 analysis for one specimen over the temperature interval where the primary TRM was reliably
605 isolated. Open (closed) symbols refer to the inclinations (declinations) in the orthogonal
606 vector diagrams. Note that the Triaxe protocol provides measurements every 5 °C and that
607 only a subset of the data (every 25 °C from 150 °C up to the highest temperature) are reported
608 in these diagrams.

609

610 **Fig. 5.** Geomagnetic intensity variations in the Balkans area for the first millennium CE.

611 Comparison of our new data (pink crosses) with three successive selections of available
612 archeointensity data obtained in the Balkans (Nachasova et al., 2007; De Marco et al., 2008a;
613 Tema et al., 2009, 2012, 2013; Spassov et al., 2010; Spatharas et al., 2011; Tema and

614 Kondopoulou, 2011; Kovacheva et al., 2014; Kondopoulou et al., 2014, 2015). All data were
615 first reduced at the latitude of Thessaloniki (40.6°N). a) Archeointensity results satisfying a
616 set of quality criteria as described in the main text. Solid symbols correspond to the data
617 obtained using pTRM-checks while open symbols refer to those obtained without such
618 magnetic mineralogy test. b) Archeointensity obtained using pTRM-checks, with results from
619 Bulgaria reported with different symbols depending of the artifacts analyzed. The red curve
620 (with yellow error band at 95% of confidence) corresponds to the prediction of the
621 archeomagnetic model A at Thessaloniki (Pavón-Carrasco et al., 2014). c) Archeointensity
622 data obtained using pTRM-checks and whose age error is < 100 years. A 5% decrease
623 accounting for the cooling rate effect was applied for the Bulgarian data obtained on bricks.
624 The mean curve of the intensity variations, with its 2- σ envelope (blue curves) was computed
625 using a sliding window of 75 years shifted every 10 years.

626

627 **Table captions**

628 **Table 1.** New archeointensity results.

629 N Frag. (n spec.): Number of retained fragments (specimen) to derive the mean intensity
630 value. $F \pm \sigma F$ (μT): mean intensity value given with its standard deviation, F Thessaloniki (μT)
631 : relocated intensity results to Thessaloniki latitude (40.6 °N).

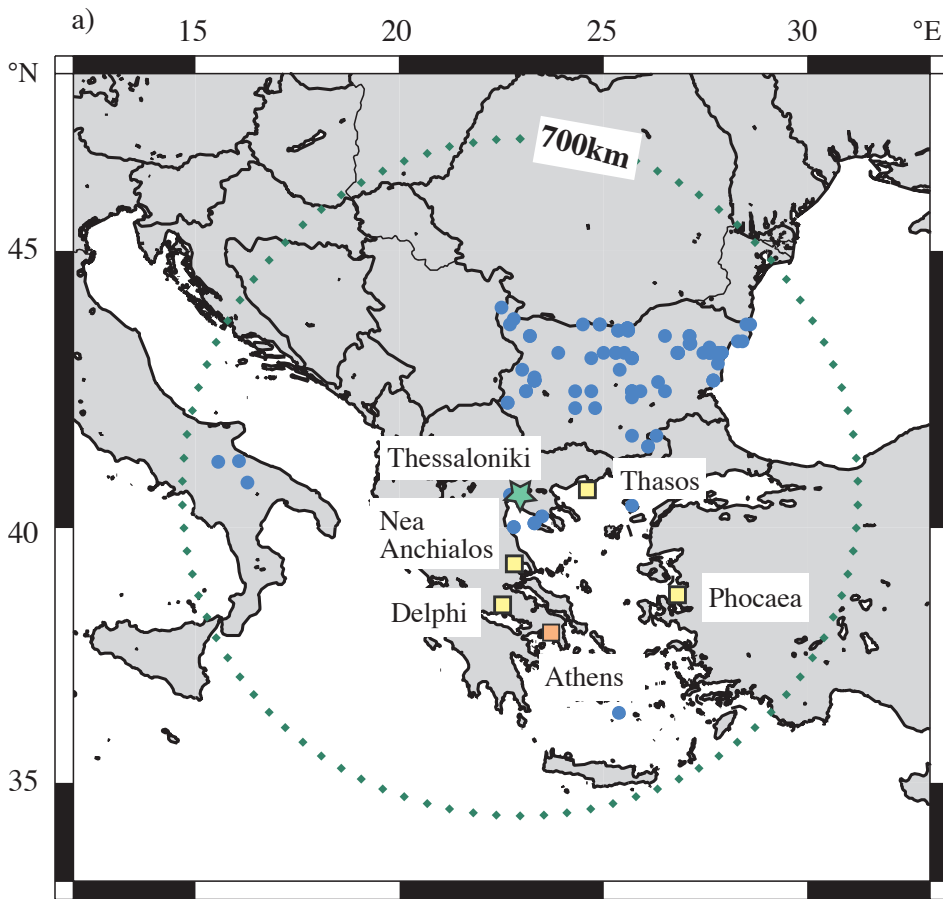

632

633 **Supplementary material:**

634 **Supplementary Table 1.** Intensity results obtained at the specimen level.

635 “Tmin-Tmax” indicates the temperature interval used for the intensity determination. “ F_{Lab} ” is
636 the intensity of the laboratory field used during the experiments. “K T1 (T1’)” gives the
637 percentage of the magnetization fraction with unblocking temperature larger than T1 (or T1’)
638 involved for the intensity determination while the “slope R’ ” is the slope of the R’(Ti) values

639 over the T_{min} - T_{max} interval. F_{Triaxe} is the intensity value at the specimen level. At the
640 fragment level, the mean intensity value is given with its standard error (resp. standard
641 deviation) when computed from two (resp. three) values. $(N1/N2/N3)^*$ indicates the number
642 of collected fragments (N1), the number of fragments whose magnetization was strong
643 enough to be measured on the Triaxe (N2) and the number of fragment retained for the
644 computation of the mean intensity value (N3).
