Abstract

In mammals, tactile information is mapped topographically onto the contralateral side of the brain in the primary somatosensory cortex (S1). Here we describe that in Robo3 mouse mutants a sizeable fraction of the trigemino-thalamic inputs project ipsilaterally rather than contralaterally. The resulting mixture of crossed and uncrossed sensory inputs creates bilateral whisker maps in the thalamus and cortex. Surprisingly, these maps are segregated resulting in a duplication of whisker representations and a doubling of the number of barrels without changes of the S1 size. Sensory deprivation shows competitive interactions between the ipsi/contralateral whisker maps. This study reveals that the somatosensory system can form a somatotopic map to integrate bilateral sensory inputs but organizes the maps in a different way than in the visual, or auditory systems. Therefore, while the molecular pre-patterning constrains their orientation and position, the preservation of the continuity of inputs defines the layout of the somatosensory maps

38

39

40

Introduction

Sensory maps in the brain need to integrate physical (topographic) and functional constraints. According to the type of sensory modality, these constraints are differently accommodated. In the somatosensory system, the sensory receptors of the periphery establish topographic replicas in the different brain relay stations, in brainstem, thalamus and cortex, with a size that is roughly proportional to functional importance of the sensory element represented (Penfield and Boldrey, 1937; Woolsey and Van der Loos, 1970).

While some of the main construction principles of these maps have been elucidated implying a collaboration of morphogenetic gradients and neural activity (Fukuchi-Shimogori and Grove, 2003; Pfeiffenberger et al., 2005; Rash and Grove, 2006), a point of continued controversy is the degree to which the initial clustering and topographical arrangement of axons carrying the inputs plays a role in map layout (Erzurumlu and Gaspar, 2012).

The contributions of molecular pre-patterning versus nearest-neighbor clustering can be tested in bilateral sensory maps that integrate bilateral signals where the inputs come from each side of the body and therefore arrive via separate routes. Manipulating the laterality of inputs can also be a way to probe the mechanisms of bilateral integration during map-building. This has been tested previously in the visual system (Rebsam et al., 2009). However, the natural overlap of the receptive fields for a portion of retinal ganglion cells between the left and right eyes could also constrain the topographic organization of the binocular visual cortex. Thus experiments done in the visual system do not allow easy disambiguation of the different mechanisms at play during the establishment of the map. Evidently, there is no such continuity and

65 overlap between the somatosensory receptive fields of the left and right sides of the

66 body. Therefore, if genetic patterning were the main factor controlling the integration

67 of bilateral sensory processing in the cortex, one would expect that changing the

68 laterality of a fraction of somatosensory inputs would create an equivalent of a

69 "binocular" region in the somatosensory cortex. To the opposite, if the map-building

70 rules maintains nearest-neighbor's interactions, one would expect that such

71 manipulation would result in a fully segregated representation of bilateral inputs in the

72 cortex. Here we examined the effect of partial uncrossing of presynaptic afferents to

73 the somatosensory thalamus in the whisker to barrel pathway of mice.

74 The sensory afferents from the whisker follicles first synapse in the brainstem

75 trigeminal complex and second order neurons in the principal sensory nucleus of the

76 trigeminal nerve (PrV) carry the whisker-specific inputs to the contralateral

77 ventroposteromedial nucleus (VPM) of the thalamus (**Figure 1A**; reviewed in

78 (Erzurumlu et al., 2010)). In the present study we focused on a conditional mouse

79 mutant in which *Robo3*, an axon guidance receptor necessary for the crossing of

80 commissural axons (Sabatier et al., 2004) is inactivated in rhombomere 3 (Renier et

81 al., 2010), the origin of most whisker-specific PrV neurons (Oury et al., 2006). The

82 conditional lack of Robo3 only caused a partial crossing defect of trigemino-thalamic

83 axons. Consequently, conditional Robo3 mutants had bilateral sensory afferents in

84 the brainstem to neocortex portion of the whisker-barrel pathway. We found that this

85 resulted in the appearance of two functional whisker maps in the thalamic relay,

86 VPM, and the barrel cortex, each receiving inputs from a different side of the animal's

87 face. Most interestingly, these maps were entirely segregated, both being confined to

88 the cortical space normally allocated to the facial whisker representation, retaining a

89 correct orientation, and topographic organization. These results suggest that the

4

90   mechanisms shaping the topographic representation of the somatosensory map

91   respect the nearest-neighbor continuity of the peripheral receptors topography, within

92   the position and orientation constrains set by the molecular pre-patterning gradients

93   in the thalamus and cortex.

94

95   **Results**

96   **Genetic perturbation of midline crossing signals and emergence of bilateral**

97   **somatosensory maps.**

98   We analyzed the whisker to barrel projection in a previously characterized mouse line

99   (Renier et al., 2010) in which the *Robo3* gene has been specifically knocked out in

100   rhombomeres 3 (r3) and r5, using the Krox20 promoter (*Krox20:Cre;Robo3^{lox/lox}*,

101   named *Robo3^{R3-5}-cKO* thereafter, while *Krox20:Cre;Robo3^{lox/+}* are named *Robo3^{R3-5}*-

102   *Het*). During development, *Robo3* is transiently expressed in r3 neurons, with an

103   expression that stops shortly after axon crossing, suggesting that it does not play a

104   role in later stages of development such as axon targeting (Badura et al., 2013;

105   Michalski et al., 2013; Renier et al., 2010). As expected, *in situ* hybridization

106   confirmed that *Robo3* expression is deleted from r3 in 12 days old (E12) *Robo3^{R3-5}*-

107   *cKO* embryos (**Figure 1B**, n= 3/3).

108   To visualize the trigemino-thalamic pathway, we crossed *Robo3^{R3-5}-cKO* mice to

109   *Tau-lox-Stop-lox-mGFP-IRES-nls-lacZ* mice (*Tau^{GFP}*) (Hippenmeyer et al., 2005). In

110   E12 controls many GFP+ axons cross the midline at the r3 and r5 level (**Figure 1B-**

111   **D)**. The ßGal nuclear reporter showed a dense distribution of Krox20+ cell bodies in

112   the ventral region of the PrV nucleus as expected from previous fate-mapping

113   experiments (Oury et al., 2006). In the *Robo3^{R3-5}-cKO;Tau^{GFP}*, the distribution of

114   ßgal+ neurons, and organization of barrelettes was normal, indicating that ROBO3

115 deletion did not alter the development of the PrV nucleus (**Figure 1C and Figure 1-**

116 **figure supplement 1**). By contrast, most of the GFP-labelled axons arising from the

117 PrV failed to cross, although they still projected rostrally towards the forebrain

118 (**Figure 1B-D**; n=3/3). At E13, coronal sections at the level of r3 showed that the

119 density of GFP+ commissural axons at the ventral midline was strongly reduced in

120 the $Robo3^{R3-5}$-$cKO;Tau^{GFP}$ but also indicated that a subset of axons still crosses

121 (**Figure 1B**). Double staining for NeuN and the nuclear cre reporter ß-gal in adult

122 sections of $Robo3^{R3-5}$-$Het;Tau^{GFP}$ mice (**Figure 1-figure supplement 1;** n=5)

123 showed that 88% NeuN+ neurons in the ventral part of PrV express ßgal but that a

124 small subset of the NeuN+ PrV neurons (10.7± 1.5%) was not ßgal+ and probably did

125 not express Cre recombinase.

126 As ephrins and their receptors have been shown to control the targeting and

127 orientation of thalamocortical projections for visual or somatosensory axons (Dufour

128 et al., 2003; Pfeiffenberger et al., 2005), we checked the pattern of *ephrin-A5* mRNA

129 expression at P0 in controls and $Robo3^{R3-5}$-cKO mutants by in-situ hybridization. The

130 expression gradients of *ephrin-A5* in the cortex and thalamus were not noticeably

131 different in the mutants compared to controls (**Figure 1E**, (n=2)) suggesting that the

132 deletion of Robo3 in the brainstem did not affect the expression of patterning cues in

133 the thalamus and cortex.

134 3D imaging of the trajectory of the trigemino-thalamic (TT) tract from the brainstem to

135 the thalamus using iDISCO (Renier et al., 2014) (**Figure 2A**) revealed that at P4, the

136 GFP+ axons had a similar trajectory in the TT tract in both the control and mutant

137 mice (n=5), although the tract appeared slightly more defasciculated in the mutants.

138 GFP+ axon terminals arborized in the VPM in both control and mutant mice and

139 formed barreloids (**Figure 2A, B; Video 1**). In all mutants and controls (n=14 for each

140 genotype), the r3-derived GFP+ (r3-GFP+) axons projected to the dorsolateral VPM

141 containing the barreloids (**Figure 2B**). An abnormal organization of the whisker

142 barreloids was noted in the mutant VPM. In controls, all the barreloid rows coincided

143 with a dense r3-GFP+ axon territory (**Figure 2B**; n=4/4), whereas in mutants two

144 distinct zones were observed (n=4/4): a lateral VPM domain containing a high density

145 of GFP+ axons and a medial VPM domain with only sparse patches of GFP+ axons

146 (**Figure 2B**). These two VPM domains contained barreloids as noted with

147 cytochrome oxidase staining and were of comparable surface area in coronal

148 sections through the middle of the VPM (0.19 ± 0.006 mm^2 for the lateral dense GFP+

149 domain and 0.18 ± 0.003 mm^2 for the medial patches of GFP+ domain, P=0.46).

150 Moreover, they were separated by a cytochrome oxidase-free septum. These

151 observations suggested that in the $Robo3^{R3-5}$-cKO mice, the VPM became split into

152 two separate domains, each with a different barreloid patterning (although the lateral

153 one contains the highest density of the r3-derived projections, and the larger

154 barreloids).

155 We anterogradely traced the PrV to VPM projections in P4 $Robo3^{R3-5}$-cKO mice

156 using carbocyanine dyes. In control mice the PrV-VPM projection was completely

157 crossed whereas in mutants the VPM received a bilateral innervation from the PrV

158 (**Figure 2C**). Moreover, the position, shape and size of the traced projections in the

159 VPM was reminiscent of the two domains described previously, suggesting that in the

160 mutants, the dense GFP+ lateral region might correspond to abnormal ipsilateral

161 projections from the PrV, while the medial patches might be originating from the

162 contralateral side.

163 These observations indicate that the mutant VPM receives segregated ipsilateral and

164 contralateral trigemino-thalamic inputs. Retrograde injections from the VPM labeled

165   cell bodies on both contralateral and ipsilateral trigeminal PrV nuclei in $Robo3^{R3-5}$-

166   *cKO* mutants (3.3 times (n=3) more cell bodies were labeled ipsilaterally than

167   contralaterally) (**Figure 2D**; n=4/4). Interestingly, the neurons projecting ipsilaterally

168   and contralaterally were mixed in the ventral PrV in the $Robo3^{R3-5}$-*cKO* mutants, in

169   contrast with the segregation of their projections seen with the anterograde tracings.

170   Overall these data suggest that a large fraction of the rhombomere 3-derived

171   trigemino-thalamic axons project ipsilaterally in $Robo3^{R3-5}$-*cKO* mutants but that

172   some still project contralaterally either because Cre recombination was incomplete or

173   occurred after crossing.

174   It is possible that the timing of arrival of the ascending axons in the VPM could

175   participate in the segregation of the ipsilateral and contralateral domains because of

176   their shorter path in the mutants. Ipsilateral axons in mutants may reach the VPM first

177   and occupy the dorso-lateral quadrant of the VPM normally populated by the larger

178   barreloids in controls. We looked at the development of the trigemino-thalamic (TT)

179   tract at E15.5 in $Robo3^{R3-5}$-*cKO;Tau^{GFP}* mutant embryos, when axons from the PrV

180   have not yet reached their targets in the VPM (**Figure 2-figure supplement 1A**, n=3)

181   (Kivrak and Erzurumlu, 2013). In this line, both ipsilateral and contralateral PrV

182   projections to the VPM are GFP+. To selectively label contralateral PrV axons, we

183   injected DiI unilaterally into the PrV. In the TT tract, red axons (DiI+ only), yellow

184   axons (double positive for GFP and DiI), and green axons (GFP+) were organized in

185   a medial to lateral gradient (**Figure 2-figure supplement 1A**, n=3), suggesting that

186   ipsilateral and contralateral axons in the TT tract might be pre-sorted before reaching

187   their target. Ipsilateral (green only) axons were always seen next to contralateral

188   axons (red and yellow) in the TT tract up to the rostral-most sections containing the

189   endings/growth cones of the developing axons. Therefore, ipsilateral axons had no

190 measurable lead over contralateral axons before reaching the VPM at this stage.

191 Indeed, in both $Robo3^{R3-5}$-Het;Tau^{GFP} and $Robo3^{R3-5}$-cKO;Tau^{GFP} mutants E18

192 embryos, the TT have reached the VPM and its terminals fill the whole dorsal region

193 (Kivrak and Erzurumlu, 2013) (**Figure 2-figure supplement 1B**, n=3). However, the

194 precise timing of arrival for the contralateral and ipsilateral axons in the mutant VPM

195 is difficult to assess. While we did not find evidence for a delayed arrival of the

196 contralateral TT projections in the VPM, we cannot rule out that ipsilateral projections

197 reach their targets earlier and hence have a competitive advantage to innervate the

198 VPM.

199 To determine the 3D organization of the VPM map in the $Robo3^{R3-5}$-cKO mutants,

200 and the origin of the GFP+ patches, we performed whole-mount imaging of brains

201 from $Robo3^{R3-5}$-cKO;Tau^{GFP} mutants and heterozygous controls at P8 using iDISCO

202 (**Figure 3**)(Belle et al., 2014; Renier et al., 2014). A suitable angle was determined

203 for the optimal projection of the barreloids in the thalamic whisker map onto a plane:

204 3D datasets where oriented at a 45° oblique angle from both coronal and horizontal

205 planes (**Figure 3A, Figure 3-figure supplement 1A and Video 2**). In the $Robo3^{R3-5}$-

206 cKO;Tau^{GFP} mutants, the GFP dense and patched regions were manually segmented

207 to show their respective 3D domains. In both regions, barreloids were organized in

208 rows reminiscent of the control VPM map (**Figure 3A and Figure 3-figure**

209 **supplement 1B**, n=3).

210 To determine whether each region corresponded to a distinct whisker map we

211 performed unilateral lesions of the infraorbital nerve (ION) at P0 and the GFP+

212 projections in the VPM were imaged at P8. In control mice, the unilateral ION lesions

213 caused a fusion of the barreloids in the contralateral VPM (**Figure 3B and Figure 3-**

214 **figure supplement 1C**; n=3**).** In mutants barreloid-fusion was found in both the

215 ipsilateral and the contralateral VPM: ipsilaterally, in the GFP-dense region, and

216 contralaterally in the GFP-patched region (**Figure 3B**, n=5). This indicated that, as

217 suggested by the tracing experiments, the GFP dense region in the VPM receives

218 ipsilateral inputs from the PrV, whereas the GFP-patched region receives

219 contralateral inputs. This also demonstrated that the GFP-patched region carries

220 somatosensory inputs from the infraorbital branch of the trigeminal nerve. Moreover,

221 in addition to the fusion of the barreloids, the thalamic map that sustained sensory

222 deprivation was reduced in size, while the adjacent non-deprived map was enlarged

223 (**Figure 3C**, n=5). This showed that sensory-activity-based competition defines the

224 final space allocated to each map in the mutant VPM.

225 To verify whether both maps in the VPM received inputs from the periphery, we

226 performed an intact brain c-Fos immunolabeling in control and mutant mice whose

227 whiskers were shaved on the left side, and b, d rows were spared on the right side

228 (n=3). The intact brain immunolabeling gave us the opportunity to navigate the

229 complex 3D organization of the VPM using arbitrary oblique projection planes

230 (**Figure 4A**). In controls, two bands of c-Fos+ cells were seen contralateral to the

231 spared whiskers, revealing the B and D rows barreloids (**Figure 4B**). In $Robo3^{R3-5}$-

232 *cKO* mice, a dual band pattern in the VPM was seen on both sides of the brain. In the

233 ipsilateral VPM, the bands were visible on the same intersecting plane as controls.

234 On the contralateral VPM, the bands of activity were visible on a a more medial

235 plane, at the edge of the VPM annotation.

236 Overall these experiments provide a model for the organization of the VPM in

237 $Robo3^{R3-5}$-*cKO* mutant mice (**Figure 3D** and **Figure 4C**). In the mutant VPM, sensory

238 inputs from the ipsilateral PrV establish a dorsolateral map, with dense projections.

239 Adjacent to this map, inputs from the contralateral PrV project to the dorso-medial

240   VPM as discrete patches. These 2 thalamic maps are organized in rows, reminiscent

241   of the normal thalamic map. Our finding that whisker stimulation triggers activity-

242   related expression in the 2 VPM maps in the mutant suggests that the barreloid

243   organization is functional (**Figure 4C**).

244

245   **Formation of bifacial cortical maps**

246   Next, we determined how the VPM organization in the mutant influences the

247   formation of the somatosensory map in the cerebral cortex. Tangential sections

248   through layer 4 were stained for cytochrome oxidase and Vglut2 immunoreactivity to

249   label thalamocortical afferents (Nahmani and Erisir, 2005) (**Figure 5A and Figure 5-**

250   **figure supplement 1A**). A striking abnormality in the layout of thalamic afferents was

251   noted in the posteromedial barrel subfield (PMBSF, which corresponds to the

252   representation of the large whiskers) of S1 in *Robo3^{R3-5}-cKO* mice (n=5/5; **Figure**

253   **5A**). Large barrels were extra-numerous (52±2 barrels in mutant PMBSF *vs.* 33±0 in

254   controls), and were reduced in size (0.04mm^2 ± 0.01 per barrel in mutants, compared

255   to 0.09mm^2±0.02 in controls, P<0.0001). Moreover, they were arranged into 8 rather

256   than the usual 5 whisker rows, with a clear delineation of two separate cortical zones,

257   a central zone, and a peripheral zone, each containing distinct barrel rows (**Figure**

258   **5A and Figure 5-figure supplement 1-3**). These abnormalities were similar in both

259   hemispheres and at all ages analyzed (with only slight individual variations; n=25/25;

260   **Figure 5-figure supplement 1-3**). To map the functional whisker representation in

261   this unusual map, we monitored the activation of the immediate early gene c-Fos

262   following a one-hour exposure to an enriched sensory environment (Staiger et al.,

263   2000). In mice with unilateral trimming of the whiskers (**Figure 5B**) strong c-Fos

264   labeling is normally observed only in the S1 contralateral to the intact whiskers. In

265   *Robo3^R3-5^-cKO* mice with unilateral whisker trimming, c-Fos was activated in the

266   PMBSF of both hemispheres (**Figure 5B**). Contralateral to the intact whiskers, c-Fos

267   activation was visible in the peripheral barrel rows (contra domain; **Figure 5B**).

268   Ipsilateral to the intact whiskers, a mirror image was noted with c-Fos activation in

269   the central barrel rows (Ipsi domain; **Figure 5B**). In both contralateral and ipsilateral

270   patterns, c-Fos+ cells were detected in all layers from the columns of the stimulated

271   barrels (**Figure 5B-figure supplement 3B**). These results showed that in *Robo3^R3-5^*-

272   *cKO* mice, the crossed and uncrossed trigemino-thalamic inputs are mapped as two

273   segregated domains, the ipsilateral one nested within the contralateral map (**Figure**

274   **5B**).

275

276   **Orientation and polarity of the maps.**

277   The segregation of the two maps led to the question of its topographic organization.

278   Two scenarios are possible: i) the thalamic afferents follow topographic molecular

279   guidance cues expressed in the cortex, with complementary receptor expression in

280   the thalamus; in this case one would expect that neighboring whiskers of the ipsi-

281   and contralateral map lie in register with one another; ii) the thalamic afferents are

282   clustered following sensory activity-based rules leading functionally coordinated

283   afferents to cluster together; in this scenario, the topographical rule of near neighbors

284   would prevail over molecular gradients.To analyze the topographic alignment of the

285   crossed and uncrossed somatosensory maps we monitored c-Fos expression in S1

286   after clipping all whiskers except one row or one arc of whiskers on one side (**Figure**

287   **5C** and data not shown). When the 5 posterior most whiskers of the whisker pad (A1-

288   E1; **Figure 5C**) were left intact in control mice, this resulted in the activation of c-Fos

289   in a caudal arc of 5 barrels exclusively in the contralateral S1 (**Figure 5C**). Likewise,

290   when the second whisker row (B1-B4; **Figure 5C**) was left intact, the corresponding

291   row of barrels was activated in the contralateral S1 (**Figure 5C**). In mutants, c-Fos

292   activation was bilateral, with a labeling in both the central (ipsi) and peripheral

293   (contra) PMBSF domains (**Figure 5C**). The general orientation of the two nested

294   maps was similar and resembled that of control mice likely due to the patterning

295   activity of morphogens that determine the polarity of the map (Fukuchi-Shimogori and

296   Grove, 2001; 2003). However, unlike the visual or auditory bilateral maps, we

297   observed that there were discontinuities in the organization of the bilateral

298   somatotopic map, such as a lack of topographic proximity of the ipsi/contra

299   representation for a given barrel or barrel row. Rather, there appeared to be a clear

300   separation and independence of the ipsi- and contralateral inputs. Taken together,

301   these results favor the hypothesis that nearest-neighbor's interactions prevail to

302   some extent over the molecular pre-patterning to organize a continuous

303   representation of the periphery for each map. However, the molecular gradients still

304   contribute to maintain the general orientation of the maps.

305

306   **Competition between ipsi- and contralateral inputs for cortical space**

307   The space occupied by the barrel map was not increased in mutants (2.32 ± 0.05 mm^2

308   in controls *vs* 1.90 ± 0.12 mm^2 in mutants, P=0.04) unlike in other mouse models with

309   duplication of the S1 map where a second S1 map is formed at the expense of other

310   cortical areas (Fukuchi-Shimogori and Grove, 2001; 2003). This suggested that the

311   ipsi- and contralateral thalamic inputs compete to occupy a defined cortical space in

312   S1. Accordingly, individual barrels in mutants were roughly half the size ($44\pm 2\%$) of

313   controls. As with the VPM, we looked again at the consequences of unilateral

314   deprivation of whisker inputs induced by a neonatal (P1) lesion of the ION (Waite and

315   Cragg, 1982). In control mice, barrel-fusion was observed in the S1 contralateral to

316   the lesion (**Figure 6A**; n=3/3). In mutants, barrels fused in the maps corresponding to

317   the ipsi- and contralateral representations of the lesioned whisker pad (**Figure 6A**;

318   n=5/5). Furthermore, the representation of the unlesioned side expanded at the

319   expense of the fused-map. This suggests that there is a sensory activity-dependent

320   competition for cortical space between the ipsilateral and contralateral sensory inputs

321   in the mutant S1.

322

323   Finally, we checked whether the ipsilateral and contralateral maps were functionally

324   isolated. We took advantage of the ClearMap pipeline (Renier et al., 2016) to

325   compare c-Fos activity patterns in the whole brain in an unbiased way , in the

326   unilateral whisker stimulation protocol (n=3 per group) (**Figure 7A and Figure 7-**

327   **figure supplement 1**). We looked for brain regions that exhibited left-right

328   differences that were opposite in controls and mutants. As expected, the barrel

329   cortex and VPM exhibited statistically significant differences between the shaved and

330   stimulated sides of the brain, that were opposite between controls and mutants

331   (**Figure 7A**). Of note, the column of activity detected in d-row registered precisely in

332   the same position in control and mutants, showing that the absolute position of the d

333   row in the brain is the same in the aberrant ipsilateral map of the mutant mice than in

334   controls. We then isolated c-Fos+ cells from the upper cortical layers (n=4). In upper

335   layers, contrary to layer 4, activity patterns are not restricted to the stimulated barrels

336   (**Figure 7B**), but expand over adjacent barrels, due to downstream cortical

337   integration (Kaliszewska et al., 2012; Peron et al., 2015). We looked at the effect of a

338   patterned sensory deprivation created by trimming rows b and d on one side and

339   shaving all whiskers on the other side. Expansion of c-Fos+ cells was observed

340 within both maps between activated rows in the upper cortical layers 2-3 (**Figure 7B**),

341 but not across the boundaries of each map. This suggests that the ipsilateral and

342 contralateral whisker maps have little to no direct horizontal integration in the upper

343 cortical layers.

344

345

346 **Discussion**

347 Here we show that uncrossing a sizeable fraction of the trigemino-thalamic axon

348 tracts results in an unexpected anatomical and functional organization in the

349 thalamus and neocortex: a duplication of the facial whisker representation with two

350 segregated maps sharing the same cortical space allotted to somatosensory

351 function. If the targeting of the ascending axons was solely organized in a point-to-

352 point manner by patterning gradients in the thalamus and cortex, this genetic

353 manipulation should have resulted in the formation of an interspersed "biwhisker"

354 representation of the whiskers in both thalamic and cortical relays. Instead, we

355 observed a complete segregation of the ipsi and contralateral whisker maps, each

356 map following the spatial continuity of inputs from the whiskers. However each map

357 retained a correct orientation and topographic organization. This shows that genetic

358 pre-patterning and the preservation of the continuity of inputs interact to control

359 respectively the position and layout of the somatosensory maps. The absence of left-

360 right mixing of inputs in the $Robo3^{R3-5}$-cKO mutant somatosensory cortex also

361 suggests that the mechanisms allowing the integration of bilateral inputs in the visual

362 cortex might be absent in the somatosensory cortex.

363 The effect of uncrossing commissures has been studied in the same conditional

364 Robo3 mutant in other systems: the olivo-cerebellar projections (Badura et al., 2013)

365 and the auditory projections from the cochlear nucleus to the medium nucleus of the

366 trapezoid body (Michalski et al., 2013). In these two studies, it was found that

367 affecting the laterality of the projections did not affect the topographic targeting of the

368 uncrossed axons. However, in the case of the calyx of Held, the maturation of the

369 uncrossed synapses was delayed (Michalski et al., 2013). It is unclear whether

370 midline crossing changes the molecular expression profile of the axons to promote

371 the synaptic maturation or whether this is an indirect effect of an incorrect integration

372 within an otherwise normal network. It would be important to check the physiological

373 properties of the ipsilateral map, especially because this new model provides the

374 opportunity to study the cortical integration of an abnormal circuit.

375 The absence of bilateral integration between the two maps in the cortex of *Robo3*

376 mutants strikingly differs from what is observed in the binocular region of the visual

377 cortex (Sato and Stryker, 2008). The particular organization of the two embedded

378 whisker maps emphasizes an important characteristic of the somatosensory system

379 which combines two different mapping rules, the first being the continuous

380 topographic representation of the body surface, the second being an organization

381 into distinct functional units. The organization of bilaterality in the somatosensory

382 cortex happens differently when forced in the *Robo3^{R3-5}-cKO mice* than in the normal

383 visual cortex. This raises the tantalizing possibility that specific molecular and

384 activity-based mechanisms absent from the somatosensory system have appeared in

385 the visual system to promote the integration of bilateral information in the cortex, and

386 could therefore be an evolutionary mechanism governing how sensory information is

387 processed in *Bilateria*.

388

389 **Orientation of representations and cortical plasticity**

390   Contrary to previous observations of experimental map duplication (Fukuchi-

391   Shimogori and Grove, 2001) the present orientation of the two whisker maps was

392   similar in the general rostrocaudal and mediolateral axes, indicating that matching

393   gradients of guidance molecules and their receptors was most likely unchanged,

394   which was confirmed for ephrin-A5 (**Figure 1E**). This contrasts with the mirror image

395   organization of the sensory maps obtained when inducing novel sources of molecular

396   gradients in the somatosensory cortex (Fukuchi-Shimogori and Grove, 2001). This

397   also contrasts with observations of map duplication in the visual system, caused by a

398   change in the retinal axon crossing at the midline (Petros et al., 2008; Rebsam et al.,

399   2009), by lack of one eye (Trevelyan et al., 2007) or by lack of one hemisphere

400   (Muckli et al., 2009).

401   The normal orientation of the ipsilateral map in the mutants is surprising. One might

402   have expected that switching laterality of the normally crossed projections would flip

403   the axis of the ipsilateral map from the contralateral map to account for the chiral

404   organization of the left and right sides of the face. As both maps in the mutants

405   respect the normal orientation, the ascending tract from the ipsilateral side may either

406   undergo a torsion en route to the VPM to correct the orientation based on molecular

407   gradients present in the lemniscal pathway. Alternatively, the correction of the

408   orientation may occur only at the target site in the VPM based on the gradients of

409   expression of Eph receptors/ephrin ligands in a process akin to the visual tectum

410   (Feldheim et al., 1998; Tessier-Lavigne, 1995). If true, this hypothesis implicates the

411   presence of additional mechanisms of axonal pruning and refinement as seen during

412   the post-targeting development of visual projections (Nakamura and O'Leary, 1989;

413   Simon et al., 2012) to correct the final orientation of the ipsilateral map.

414 In conclusion, although the initial wiring of the brain largely relies on genetically

415 encoded processes, our results further illustrate the remarkable plasticity of the

416 mammalian brain and its ability to accommodate changes in afferent wiring in

417 evolution to create new maps and bilateral representations, and also its ability, in the

418 context of developmental brain disorders, to compensate for major axon guidance

419 defects that otherwise would lead to severe brain dysfunction (Jen et al., 2004;

420 Muckli et al., 2009; Williams et al., 1994).

421

422 **Materials and Methods**

423 *Mice*

424 All animal procedures were carried out in accordance to institutional guidelines

425 (UPMC, Charles Darwin ethic committe and INSERM). Mice were anesthetized with

426 Ketamine (Virbac) and Xylazine (Rompun). The day of vaginal plug is embryonic day

427 0 (E0) and the day of birth corresponds to postnatal day 0 (P0).

428 The Robo3 conditional knockout, *Krox20:Cre* knock-in and *Tau^{GFP}* lines were

429 previously described (Hippenmeyer et al., 2005; Renier et al., 2010; Voiculescu et al.,

430 2000). Unless otherwise mentioned, controls were *Robo3$^{lox/lox}$* or

431 *Krox20:Cre;Robo3$^{lox/+}$* animals. Double heterozygotes were always similar to wild-

432 type mice. Mice were genotyped by PCR.

433 The following primers were used for genotyping: the conditional *Robo3* allele, 5'-CCA

434 AGG AAA AAC TTG AGG TTG CAG CTA G-3' and 5'-GAT TAG GGG AGG TGA

435 GAC ATA GGG-3', the *Krox20:Cre* allele, 5'-AGT CCA TAT ATG GGC AGC GAC-3'

436 and 5'-ATC AGT GCG TTC GAA CGC TA-3', the T*au^{GFP}* allele, 5'-GAG GGC GAT

437 GCC ACC TAC GGC AAG-3' and 5'-CTC AGG GCG GAC TGG GTG CTC AGG-3'.

438 All PCR run have 34 cycles with an annealing temperature of 58°C.

439 In the *Tau^GFP* line, upon Cre recombination in neurons, the Stop cassette is excised

440 leading to the permanent expression of a myristoylated GFP in axons and of ß-

441 galactosidase in nuclei (Hippenmeyer et al., 2005).

442

443 *Histology and immunocytochemistry*

444 Mice were perfused transcardially with a 4% PFA in 0.12 mM phosphate buffer.

445 Cortices were flattened between microscope slides and post-fixed in 4% PFA and

446 vibratome (Leica) sectioned at 50μm. Hindbrains and thalamus were post-fixed in 4%

447 PFA, cryoprotected in 30% sucrose and sectioned at 35μm with a freezing microtome

448 (Microm).

449 For cytochrome oxidase staining (Melzer et al., 1994), sections were incubated at

450 room temperature for 24 hours in 10% sucrose, 0.3g/L cytochrome C from equine

451 heart (Sigma), 0,02g/L catalase from bovine liver (Sigma) and 0.25g/L DAB (Sigma).

452 The endogenous fluorescence of the GFP in *Krox20:Cre;Tau^GFP* was not affected

453 after the treatment and could be imaged on the same sections, however the GFP

454 signal was further enhanced by immunostaining.

455 For immunohistochemistry, neonatal and adult brains were processed as described

456 previously (Marillat et al., 2002). The following primary antibodies were used: guinea

457 pig anti-Vglut2 (1:1000, Millipore AB-2251), rabbit anti-βGal (1:1000, 55976 Cappel),

458 rabbit anti-c-Fos (1:1000, sc-52 Santa-Cruz on sections, or 1:2000, 226-003 Synaptic

459 Systems, for iDISCO+ studies), rabbit anti-GFP (1:300, A11122 Invitrogen on

460 sections), chicken anti-GFP (1:800, ab13970 Abcam on sections or 1:2000, GFP-

461 1020 Aves for iDISCO studies). The following secondary antibodies were used on

462 sections: Donkey anti-mouse, anti-rabbit and anti-guinea pig coupled to CY3 or CY5

463 (1:600, Jackson Laboratories), donkey anti-mouse, anti-rabbit and anti-chicken

464   coupled to Alexa Fluor 488, 568 or 657 (1:600, Invitrogen) for sections and iDISCO

465   studies. Sections counterstained with Hoechst 33258 (10 µg/mL, Sigma)

466   Sections were examined with a fluorescent microscope (DM6000, Leica) equipped

467   with a CoolSnapHQ camera (Roper Scientific), a confocal microscope (FV1000,

468   Olympus), or a slide scanner (Nanozoomer, Hamamatsu).

469

470   *iDISCO+ processing and light sheet microscopy*

471   Adult mice or P4, P8 pups were euthanized with a rising gradient of CO_2 and fixed

472   with an intracardiac perfusion of 4% PFA in PBS. All harvested samples were post-

473   fixed overnight at 4°C in 4% PFA in PBS.

474   Fixed samples were washed in PBS for 1h twice, then in 20% methanol (in ddH_2O)

475   for 1h, 40% methanol for 1h, 60% methanol for 1h, 80% methanol for 1h, and 100%

476   Methanol for 1h twice. Samples were then bleached with 5% H_2O_2 (1 volume of 30%

477   H_2O_2 for 5 volumes of methanol, ice cold) at 4°C overnight. After bleaching, samples

478   were re-equilibrated at room temperature slowly and re-hydrated in 80% methanol in

479   H_2O for 1h, 60% methanol / H_2O for 1h, 40% methanol / H_2O for 1h, 20% methanol /

480   H_2O for 1h, and finally in PBS / 0.2% TritonX-100 for 1h twice.

481   Pre-treated samples were then incubated in PBS / 0.2% TritonX-100 / 20% DMSO /

482   0.3M glycine at 37°C for 36h, then blocked in PBS / 0.2% TritonX-100 / 10% DMSO /

483   6% donkey serum at 37°C for 2 days. Samples were then incubated in primary

484   antibodies: chicken anti-GFP (1:2000, Aves GFP-1020), rabbit anti-c-Fos (, 1:2000,

485   Synaptic Systems, 226-003) in PBS-Tween 0.2% with heparin 10µg/mL (PTwH) / 5%

486   DMSO / 3% donkey serum at 37°C for 4 to 7 days. Samples were then washed in

487   PTwH for 24h (5 changes of the PTwH solution over that time), then incubated in

488   secondary antibody donkey anti-rabbit-Alexa647 from Invitrogen or donkey anti-

489   chicken from Jackson Immunoresearch at 1:500 in PTwH / 3% donkey serum) at

490   37°C for 4 to 7 days. Samples were finally washed in PTwH for 1d before clearing

491   and imaging. Immunolabeled brains were dehydrated in 20% methanol (in ddH$_2$O) for

492   1h, 40% methanol / H$_2$O for 1h, 60% methanol / H$_2$O for 1h, 80% methanol / H$_2$O for

493   1h, and 100% Methanol for 1h twice. Samples were incubated overnight in 1 volume

494   of methanol / 2 volumes of dichloromethane (DCM, Sigma 270997-12X100ML) until

495   they sank at the bottom of the vial (plastic Eppendorf tubes were used throughout the

496   process). The methanol was then washed for 20min twice in 100% DCM. Finally,

497   samples were incubated (without shaking) in DiBenzyl Ether (DBE, Sigma 108014-

498   1KG) until clear (about 30min) and then stored in DBE at room temperature.

499   Cleared samples were imaged in sagittal orientation (right lateral side up) on a light-

500   sheet microscope (Ultramicroscope II, LaVision Biotec) equipped with a sCMOS

501   camera (Andor Neo) and a 2X/0.5 objective lens (MVPLAPO 2x) equipped with a

502   6mm working distance dipping cap. Version v144 of the Imspector Microscope

503   controller software was used. The microscope is equipped with LED lasers (488nm

504   and 640nm) with 3 fixed light sheet generating lenses. Scans were made at the 0.8X

505   zoom magnification (1.6X effective magnification), with a light sheet numerical

506   aperture of 0.1. Emission filters used are 525/50 and 680/30. The samples were

507   scanned with a step-size of 3µm using the continuous light sheet scanning method

508   with the included contrast blending algorithm for the 640nm channel (20 acquisitions

509   per plane with a 50ms exposure), and without horizontal scanning for the 480nm

510   channel (50ms exposure). To speed up the acquisitions, both channels where

511   acquired in two separate scans.

512   Maximum 3D projections in **Figure 2A** and all panels of **Figure 3**, **4** and **7B** were

513   performed   using   Imaris   (Bitplane,   http://www.bitplane.com/imaris/imaris),   and

514   generated from manual 3D segmentation of the raw data using the surface tool.

515   ClearMap (Renier et al., 2016) (https://www.idisco.info) was used to quantify and

516   register c-Fos+ cells in **Figure 7A**. Parameters were set as previously described, and

517   automated isolation of the cortex was done using the scripts available online.

518

519   *In situ hybridization*

520   Antisense riboprobes were labeled with digoxigenin-11-D-UTP (Roche Diagnostics)

521   as described previously (Marillat et al., 2002) by in vitro transcription of mouse

522   cDNAs encoding *robo3* or an exon specific probe of *robo3* targeting the floxed region

523   (Renier et al., 2010).

524

525   *DiI tracing*

526   4% PFA fixed P4 pups were injected with small crystals of 1,1'-dioctadecyl-3,3,3',3'-

527   tetramethylindocarbocyanine perchlorate (DiI, Invitrogen) and 4-(4-

528   (dihexadecylamino)styryl)-*N*-methylpyridinium iodide (DiA, Invitrogen) using glass

529   micropipettes. For anterograde tracing, the dye crystals were injected unilaterally in

530   the PrV. For retrograde tracing of the PrV nuclei, the cortices were removed to

531   expose the thalamus and DiI or DiA crystals were at the level of the VPM.

532   Brains were kept at 37°C for 4 weeks. Brains were cut in 80 µm sections with a

533   vibratome (Leica) and counterstained with Hoechst.

534

535   *Infraorbital nerve lesions*

536   P0-P1 pups were cold anesthetized, and an incision was made between the whisker

537   pad and the eye. The nerve was cut with scissors under a dissecting scope. The

538   pups were allowed to recover for 10 days and then perfused.

539

c-Fos expression and whisker activity

541 P20-P30 mice were anesthetized with ketamine, and all whiskers were trimmed on

542 the left side. In different experiments, either all whiskers were spared on the right

543 side, or only selected whisker rows or arcs were spared. Mice were allowed to

544 recover from anesthesia for 6 to 12 hours, and then left alone in a large (1m x 60cm)

545 "enriched" cage in the dark for 1 hour before being perfused and processed for c-Fos

546 immunostaining.

547

Quantifications and statistical analysis

549 Areas were calculated with NDPview (Hamamatsu) from cytochrome oxidase

550 staining at P10 or Vglut2 stainings when done in adults. For quantification of map

551 areas from P10 flattened cortices, the surface in controls was limited to the first 4

552 barrels in row a, 4 in row b, 6 in row c, 7 in row d and 8 in row e. In

553 *Krox20:Cre;Robo3$^{lox/lox}$* mutants, the central (ipsi) map area comprises the domain

554 bordered by a thick Vglut2-negative boundary. The peripheral (contra) map area was

555 limited to the barrels located immediately above and below the border of the central

556 ipsi map. To determine individual barrel areas in adults, only the largest

557 unambiguous barrels were measured (first 3 barrels for rows e,d,c and first barrels

558 for rows a and b). Areas where assessed on the tangential section showing the most

559 complete map of the PMBSF.

560 The areas of the VPM nucleus were calculated with NDPview from frontal sections of

561 P4 *Krox20:Cre;Tau^{GFP}* mice stained with cytochrome oxidase and immunostained for

562 GFP, at a mid-level of the VPM, where the barreloids organization was the most

563 obvious.

564 Results are presented as means ± SEM. Differences of the means between two

565 sample sets were assessed by two-tailed non-parametric Mann-Whitney test.

566 Statistics were carried out with Prism (Graphpad software).

690   **Figure legends**

691

692   **Figure 1. Rewiring of r3 and r5 derived hindbrain projections to**
693   **midbrain/forebrain projections in *Robo3^{R3-5}-cKO* mice.**
694   (**A**) Schematic representation of the mouse whisker to barrel somatosensory
695   pathway. (**B**) Top panels: in situ hybridization (*ish*) with a *robo3* probe on coronal
696   sections at rhombomeres 3 and 2 (r3, r2) level in E12 embryos. No staining is
697   observed in *Robo3^{R3-5}-cKO* mice in r3. Trigeminal ganglion (V) neurons do not
698   express *Robo3*. Bottom panels: coronal sections at r3 level in E13 *Robo3^{R3-5}-*
699   *Het;Tau^{GFP}* or *Robo3^{R3-5}-cKO;Tau^{GFP}* embryos stained for GFP. GFP+ commissures
700   are strongly reduced in mutants, but a few axons are still crossing (arrows)**. (C**)
701   Cytochrome oxidase staining (Cyt. ox.), and ßGal, GFP co-Immunostaining of
702   coronal sections of P4 *Robo3^{R3-5}-Het;Tau^{GFP}* or *Robo3^{R3-5}-cKO;Tau^{GFP}* brains at the
703   level of the brainstem principal trigeminal nucleus (PrV), showing the barrellettes.
704   Rows a to e are indicated. The barrelette patterns and ßGal+ cells distribution is
705   similar in control and *Robo3^{R3-5}-cKO* mutant mice. aVCN: anterior ventral cochlear
706   nucleus. (**D**) flat-mount view and scheme of the hindbrain of E12 *Robo3^{R3-5}-*
707   *Het;Tau^{GFP}* or *Robo3^{R3-5}-cKO;Tau^{GFP}* embryos. Commissures are strongly reduced at
708   r3 and r5 levels in mutants but a subset of axons still cross in r3 (arrowheads). GFP+
709   axons still project rostrally towards the midbrain. (**E**) Coronal sections at the level of
710   the forebrain VPM thalamic nucleus and barrel cortex of P0 *controls* or *Robo3^{R3-5}-*
711   *cKO* brains hybridized with an *ephrin-A5* probe, showing the expression gradients of
712   the molecule, which are unaffected by the conditional deletion of the Robo3.
713   Scale bars are 400µm, except ish and Cyt. ox (100µm) and **E** (500µm).
714
715   **Figure 2. Organization of the projections to the VPM**
716   (**A**) Whole-mount immunostaining for GFP in *Robo3^{R3-5}-Het;Tau^{GFP}* and *Robo3^{R3-5}-*
717   *cKO;Tau^{GFP}* P4 brains cleared with iDISCO. Dorsal projections (left) and lateral
718   projections (right) are shown for each case. The Trigemino Thalamic tract has been
719   color-coded in gray, while the rest of the GFP signal is in green. (**B**) Coronal sections
720   of P4 mouse brain through the sensory thalamus (VPM) stained for cytochrome
721   oxidase. In *Robo3^{R3-5}-Het;Tau^{GFP}* mice, GFP+ axons project to the barreloid area of
722   the VPM. In *Robo3^{R3-5}-cKO;Tau^{GFP}* mice barreloids are found in two regions, a lateral
723   one containing most of the GFP+ axons and a medial one (arrows) containing only a
724   few patches of GFP axons. (**C**) P4 mice injected bilaterally with DiI and DiA at the
725   level of the PrV nucleus. Sections were collected at the level of the VPM. In controls,
726   the PrV-VPM projection is entirely crossed. In mutants, the VPM receives bilateral
727   inputs from the ipsilateral and contralateral PrV. (**D**) P4 hindbrain cross sections at
728   the level of the PrV in controls and mutants after unilateral injections of DiA and DiI in
729   the VPM (depicted in the schematics). In controls, PrV trigemino-thalamic projection
730   neurons are labeled by the dye injected in the contralateral VPM. In mutants, the
731   dorsal PrV also has only contralaterally labeled neurons, whereas the ventral PrV
732   contains interspersed ipsilaterally and contralaterally labeled neurons.
733   Scale bars are 300µm.
734
735
736   **Figure 3. Structure of the VPM maps revealed by ION lesions**

737 Whole-mount scans of 3DISCO cleared P8 *Robo3^{R3-5}-Het;Tau^{GFP}* and *Robo3^{R3-5}-*
738 *cKO;Tau^{GFP}* brains immunostained for GFP. Optical sections and 3D oblique
739 projections are presented. (**A**) Control and mutant brains, ION intact. The oblique
740 projection reveals the topographic barreloid organization in controls (left panels) or
741 mutants (right panels). In the mutant, the dense and patched domains of GFP+
742 axons (green and red respectively) were manually segmented. (**B**) Mutant brains,
743 unilateral ION lesions. The data are presented as in **A**. On the side contralateral to
744 the lesion, the barreloids in the patched projection map (red) are fused (n=3), while
745 the topographic organization of the barreloids in the dense GFP+ domain is still
746 visible (green). The opposite is seen on the side ipsilateral to the lesion: the dense
747 domain of GFP+ axons (green) reveals a fused map while rows of barreloids are
748 visible in the patched domain (red). (**C**) Expansion and retraction of the VPM
749 domains in P8 *Robo3^{R3-5}-cKO;Tau^{GFP}* brains after lesions. (**D**) Model of the VPM
750 organization in mutant mice deduced from the lesions experiments.
751 Scale bars are 300µm.
752
753 **Figure 4. Bilateral inputs to the VPM in Robo3R3-5-cKO mice**
754 Whole brain iDISCO+ scans from adult mice immunolabeled for c-Fos. The whiskers
755 were shaved on the left side, and B, D rows were spared on the right side. **A**
756 Presentation of the projection plane used in the following panels: a 45° oblique (from
757 both coronal and sagittal) 50µm projection plane was positioned to intersect with the
758 VPM annotation (in red). **B** Details of the c-Fos pattern in the VPM of *Robo3^{R3-5}-Het*
759 and *Robo3^{R3-5}-cKO* mice on each side. In controls, two bands of c-Fos+ cells were
760 seen on the side contralateral to the spared whiskers, revealing the B and D rows
761 barreloids. In *Robo3^{R3-5}-cKO* mice, a dual band pattern in the VPM was seen on both
762 sides of the brain. On the ipsilateral side, the bands were visible on the same
763 intersecting plane as in controls. On the contralateral side, the bands of activity were
764 visible on a plane more medial, at the edge of the VPM annotation. **C** Representation
765 of the VPM organization in the *Robo3^{R3-5}-cKO* mice.
766 Scale bars are 500µm.
767
768 **Figure 5. Bilateral inputs to the barrel cortex in Robo3R3-5-cKO mice**
769 (**A**) tangential sections through the barrel cortex from P10 mice stained for anti-Vglut2.
770 Barrels are more numerous and smaller in mutants. (**B**) Tangential sections through Flat-
771 mounted cortices at the level of the barrel cortex in whisker-deprived adult mice
772 immunostained for Vglut2 and c-Fos. In controls, c-Fos+ cell density is high in the barrel
773 cortex contralateral to the intact whiskers and low on the ipsilateral side. In *Robo3^{R3-5}-*
774 *cKO* mutants, c-Fos expression is induced bilaterally in complementary domains on
775 either side of the cortex, ipsilateral and contralateral to the stimulated side. (**C**)
776 Interpretation of the results from (**B**). (**D**) Tangential sections through Flat-mounted
777 cortices at the level of the barrel cortex, in whisker-deprived adult mice immunostained
778 for Vglut2 and c-Fos. The left side of the face were fully shaved, while only the first arc
779 (left panels) or b row (right panels) were spared on the right side. Only the contralateral
780 sides are shown for controls. Mutants show bilateral patterns of c-Fos (**E**) Schematic
781 representation of the whisker map deduced from c-Fos activation patterns. (**F**) General
782 model for the wiring of the *Robo3^{R3-5}-cKO* mutant mice.
783 Scale bars are 200µm.
784
785 **Figure 6 Activity-dependent competition between ipsilateral and contralateral**
786 **inputs in mutant barrel cortex**

787   Tangential sections of controls or *Robo3^R3-5^-cKO* flat-mounted P10 cortices stained
788   for cytochrome oxidase in control conditions or after unilateral lesion of the
789   infraorbital nerve (ION) at P1. In *Robo3^R3-5^-Het* controls, the barrels do not form in S1
790   contralateral to the lesion, whereas a normal map is seen on the ipsilateral side. In
791   *Robo3^R3-5^-cKO* mutants, contralateral to the lesion, barrels form in the domain
792   processing ipsilateral inputs and ipsilateral to the lesion a barreless region is noted in
793   the domain processing ipsilateral inputs. The size of the ipsilateral map is indicated to
794   compare with the maps in unlesioned mutants and controls. Quantification of the
795   surface occupied by the large-whiskers barrels is shown on the right side.
796   Scale bars are 200µm.
797
798   **Figure 7 Cortical integration of sensory information**
799   (**A**) ClearMap analysis of the c-Fos patterns in iDISCO+ cleared brains in control and
800   mutant mice after 1h of exploration of a new environment (n=3 for each group). The
801   whiskers were shaved on the left side, and b, d rows were spared on the right side.
802   Heatmaps present averaged c-Fos+ cell densities on both sides for 3 brains for each
803   group, and the p-values maps present the voxels statistically different between the
804   left and right sides, in green when the left side is more active, in red when the right
805   side is more active. At the level of the barrel cortex, as expected the activation was
806   reversed between control and mutant maps in both the VPM and cortex, at the level
807   of the d row (arrowheads). (**B**) iDISCO+ whole-mount c-Fos immunostaining and
808   imaging of adult brains after unilateral stimulation of the rows a, c and e, manually
809   segmented by cortical layers. The pattern in the lower right panel shows the spread
810   of c-Fos+ cells between active rows, but no spill-over of activity from the contralateral
811   map to the adjacent ipsilateral map (arrows show blank rows in layers 2/3).
812   Scale bars are 400µm.
813

814
815
816 **Figure 1-figure supplement 1**
817 **Normal organization of the principal trigeminal nucleus (PrV) in *Robo3^{R3-5}-cKO***
818 **mice**
819 (**A**) Cytochrome oxidase staining of coronal sections of P4 brains at the level of the
820 PrV, showing the barrellettes. Rows a to e are indicated. The barellette pattern is
821 similar in control and *Robo3^{R3-5}-cKO* mutant mice. MV: Trigeminal motor nucleus, d:
822 dorsal PrV, v: ventral PrV. (**B**) Coronal sections at the level of the PrV in adults
823 *Robo3^{R3-5}-Het;Tau^{GFP}*, stained with anti NeuN and anti ßGal. ßGal- and NeuN+ cells
824 can be found in the ventral PrV (arrowheads).
825 Scale bars, 400µm and 100µm (**A**); 200µm and 50µm (**B**)
826
827 **Figure 2-figure supplement 1**
828 **Tract organization and timing of arrival of Ipsilateral and contralateral**
829 **projections from the Principal Trigeminal Nucleus (PrV) to the thalamus in the**
830 ***Robo3^{R3-5}-cKO* embryos.**
831 (**A**) Coronal sections of E15.5 *Robo3^{R3-5}-cKO ; tau^{GFP}* embryos (n=3) at the rostral-
832 most level where the axon bundle of the trigemino-thalamic tract (TT) is visible, in the
833 developing thalamus. Contralateral projections from the PrV are labeled with DiI, and
834 r3-PrV axons (ipsi and contra) are labeled with GFP. A medio-lateral gradient of DiI+,
835 DiI+/GFP+ and GFP+ axons is seen in the tract, suggesting that contra- and
836 ipsilateral axons are pre-organized in the tract before reaching the thalamus.
837 Moreover, both contralateral and ipsilateral axons are seen at the end of the
838 developing TT, suggesting an absence of a significant delay in the development of
839 the contralateral tract compared to the ipsilateral tract. (**B**) Coronal sections of E18
840 controls and *Robo3^{R3-5}-cKO ; tau^{GFP}* embryos (n=3) at the level of the VPM, shortly
841 after the arrival of the TT axons from the PrV. In the mutants, GFP+ terminals in both
842 the dense and sparse clusters are visible, suggesting that both ipsi- and contralateral
843 populations of PrV axons are present early in the developing VPM.
844 Scale bars are 100µm.
845
846 **Figure 3-figure supplement 1**
847 (A) Detail of the projection plane used to reveal the VPM topography in whole-mount
848 GFP labeled P8 brains cleared with 3DISCO. (**B**) Detail of the manual 3D color-
849 coding used in *Robo3^{R3-5}-cKO;Tau^{GFP}* mutant mice to highlight the different domains
850 of the VPM, based on the pattern of GFP+ terminals (dense or patched). (**C**) Effect of
851 a neonatal lesion of the infraorbital nerve (ION) in controls *Robo3^{R3-5}-Het;Tau^{GFP}*
852 mice. Barreloids are visible on the side ipsilateral to the lesion, but not on the side
853 contralateral where they are indicated as "fused".
854 Scale bars are 300µm.
855
856 **Figure 5-figure supplement 1**
857 Tangential sections through cortical layer 4 in adult flat-mounted cortices of control
858 and *Robo3^{R3-5}-cKO* mutant mice stained for Vglut2. Both left and right sides are
859 shown. In mutant animals, the organization of the barrels is similar, but variations on
860 the shape of the inner maps are seen from animal to animal, and also between left
861 and right sides. Scale bars are 500µm.
862
863 **Figure 5-figure supplement 2**

864 Quantification of the surface of major barrels from tangential sections through cortical
865 layer 4 in P30 control and *Robo3*$^{R3-5}$*-cKO* mutant mice.
866
867 **Figure 5-figure supplement 3**
868 (**A**) Tangential sections through cortical layer 4 in P10 flat-mounted cortices of control
869 and *Robo3*$^{R3-5}$*-cKO* mutant mice stained for cytochrome oxidase (Cyt. ox.). The black
870 dashed outline shows the presence of 2 domains in the mutant map, delimited by a
871 cytochrome oxidase-free band. (**B**) Coronal sections through adult brains at the level
872 of the barrel cortex in whisker-deprived mice immunostained for c-Fos and Hoechst.
