Abbreviated title: MLH1 impact on tumour fate after surgery

Abstract

Colorectal cancers (CRCs) displaying microsatellite instability (MSI) most often result from MLH1 deficiency. The aim of this study was to assess the impact of MLH1 expression *per se* on tumour evolution after curative surgical resection using a xenograft tumour model. Transplantable tumours established with the human MLH1-deficient HCT116 cell line and its MLH1-complemented isogenic clone, mlh1-3, were implanted onto the caecum of NOD/SCID mice. Curative surgical resection was performed at day 10 in half of the animals. The HCT116-derived tumours were more voluminous compared to the mlh1-3 ones ($P = .001$). Lymph node metastases and peritoneal carcinomatosis occurred significantly more often in the group of mice grafted with HCT116 ($P = .007$ and $P = .035$, respectively). Mlh1-3-grafted mice did not develop peritoneal carcinomatosis or liver metastasis. After surgical resection, lymph node metastases only arose in the group of mice implanted with HCT116 and the rate of cure was significantly lower than in the mlh1-3 group ($P = .047$). The murine orthotopic xenograft model based on isogenic human CRC cell lines allowed us to reveal the impact of MLH1 expression on tumour evolution in mice who underwent curative surgical resection and in mice whose tumour was left *in situ*. Our data indicate that the behaviour of MLH1-deficient CRC is not only governed by mutations arising in genes harbouring microsatellite repeated sequences, but also from their defect in MLH1 *per se*.

INTRODUCTION

Colorectal carcinoma (CRC) is the third most common type of cancer and the second leading cause of cancer-related death.¹ Approximately one-fourth of patients can be cured by surgery alone, whereas the remaining need to be treated with chemotherapy due to metastasis at the time of diagnosis, development of metastasis or recurrence of disease. The development of CRC involves at least three partially overlapping oncogenic pathways displaying characteristic genetic or epigenetic alterations: microsatellite instability (MSI), CpG island methylator phenotype, and chromosome instability.²⁻⁴ MSI CRCs represent about 15% of all CRC and arise due to mismatch repair (MMR) deficiency, either as a result of inherited mutations in one of the MMR genes, most often *MSH2* or *MLH1*, or, more often, through somatic epigenetic methylation of the *MLH1* promoter.^{3,5,6} Patients with MSI CRC have a better stage-adjusted prognosis than those with CRC displaying chromosome instability,^{7,8} and there is increasing evidence showing that MSI influences the response to chemotherapy,^{3,9-15} to ionizing radiation,¹⁶ and to immunotherapy.^{17,18}

It is widely accepted that MMR deficiency is not a transforming event *per se*, but that it promotes oncogenesis through accumulation of mutations arising during replication as they are left uncorrected due to MMR deficiency.^{19,20} Simple sequence repeats, also known as microsatellites, are particularly prone to insertion and deletion mutations resulting from polymerase slippage. Several genes involved in the control of cell proliferation and differentiation, and DNA damage signalling and repair carry a mononucleotide repeat,^{21,22} which is mutated in MSI CRC at a frequency higher than expected from their length, suggesting that their inactivation may participate in tumour initiation and/or progression.^{23,24} In addition to the numerous MSI-driven mutations inactivating target genes that may be considered as putative novel oncogenes,²⁵ *MLH1* deficiency itself may further contribute to tumour progression owing to its role in recombination^{26,27} and apoptosis.²⁸⁻³¹

Metastasis is a multistep process that requires the ability of tumour cells to invade the underlying tissues, survive in the circulation and colonize various organs, mostly lymph

nodes, liver and lung in the case of CRC. Most of the mutations found in CRC metastases are present in the paired primary lesion, suggesting that dissemination is an early event during cancer development.³² Hence, the potential for metastatic development of CRC possibly relies on intrinsic properties of the primary tumour.³²

Orthotopic CRC xenograft mouse models have been established by transplanting human colon cancers onto the caecum of deficient mice.³³⁻³⁶ Orthotopic xenografts are clinically more relevant than subcutaneous tumours as they may give rise to local or distant metastasis formation, in lymph nodes, in the peritoneum (carcinomatosis), or in the liver.^{34,36-41} Furthermore, orthotopic xenografts are valuable models to evaluate tumour progression after curative surgical tumour resection since they represent the possible fate of tumours arising in humans, i.e. cure (when there is no evidence of disease), local recurrence or distant metastases.^{39,40} As an example, we previously reported that specific alterations of E-cadherin expression or *TP53* in LoVo, an MSI colon cancer cell line, dramatically changed the rate of cure and metastatic behaviour after surgical resection of the tumour.³⁹

The purpose of the present study was to investigate whether *MLH1* expression *per se* had an impact on the evolution of the tumour after curative surgical resection or when left *in situ*, using a murine orthotopic xenograft model based on the *MLH1*-deficient HCT116 cell line and an isogenic *MLH1*-complemented clone.

MATERIALS AND METHODS

Cell lines

Experiments were performed on the *MLH1*-deficient colorectal cancer cell line HCT116, kindly provided by Peter Karran in June 1995 (Imperial Cancer Research Fund, Clare Hall, United Kingdom), and its *MLH1*-complemented counterpart cell line mlh1-3, obtained by transfecting the HCT116 cell line with an expression vector containing the wild-type *MLH1* cDNA, as described.⁴² Cells were regularly authenticated using the short tandem repeat

(STR) panel recommended by the International Cell Line Authentication Committee, as described in detail below. In particular, cells were typed at the beginning and at the end of the experimental procedures; the genotypes of the parental HCT116 and its *MLH1*-complemented counterpart cell line are shown in Supporting Information Table 1. Compared with the HCT116 genotype published by the American Type Cell Culture (ATCC), there are 2 minor differences, consisting of the addition of 1 bp at the longer vWA allele (22.1 instead of 22) and the partial (in HCT116) or complete (in mlh1-3) loss of the chromosome Y-specific amelogenin allele. As discussed in the Results section, such differences do not challenge the identity of the HCT116 cells used in this study, but rather underline that novel indel mutations are highly susceptible to arise during replication of the mismatch repair-deficient HCT116 cells. Cells were grown in monolayer cultures in DMEM (Dulbecco's Modified Eagle's Medium, Sigma, France), supplemented with 10% of heat-inactivated foetal bovine serum, L-glutamine (2 mM), penicillin (100 µg/mL), and streptomycin (100 UI/mL), in a humidified incubator at 5% CO₂. The mlh1-3 cell line was maintained under selective pressure by adding 100 µg/mL hygromycin, until injection into mice.

Genomic DNA extraction and STR fingerprinting

The DNeasy tissue kit (Qiagen, Hilden, Germany) was used to extract genomic DNA from cell pellets, according to the manufacturer's instructions. STR genotypes were established using eight highly polymorphic tetranucleotide STR markers (D5S818, D7S820, D13S317, D16S539, CSF1PO, THO1, TPOX, and vWA) and the Amelogenin marker that discriminates the X from the Y chromosome due to a 6-bp insertion. PCR were carried out using 0.2 mM dNTP, 0.15 mM primers (0.2 mM for D7S820), 0.5U KAPA2G Robust HotStartTaq polymerase (Kapa Biosystems, Wilmington, MA), and sense primers labeled with 6-FAM or HEX. After a 3-min step at 95°C, 35 cycles of 15 sec at 95°C, 15 sec at 55°C and 15 sec at 72°C, followed by a 1 min final extension at 72°C were performed. PCR products were diluted in formamide containing ROX-labelled 400 HD size markers (PE Applied Biosystems, Foster City, CA) and electrophoresed in 36-cm capillaries containing POP-7 on an ABI

PRISM® 3130 Genetic Analyzer (PE Applied Biosystems). The apparent sizes of the alleles were determined using the GeneMapper Analysis software (PE Applied Biosystems).

MSI analysis

MSI was investigated using four highly polymorphic CAn dinucleotide microsatellite markers located on three different chromosome arms (5q, 17p, and 18q). PCR was carried out in 20 µL using 0.2 mM dNTP, 0.5 U HotStarTaq polymerase (Qiagen), and sense primers labelled with 6-FAM (D5S107), HEX (D18S474) or NED (D17S1791, D18S1127). The primer sequences are from the Ensembl Genome System website. After a 15-min step at 95°C, 35 cycles of 30 sec at 94°C, 30 sec at 55°C and 30 sec at 72°C, followed by a 6 min final extension at 72°C, were performed. PCR products were analysed as described above for STR fingerprinting.

Detection of frameshift mutations

The regions encompassing the repeated mononucleotide sequences contained in 26 selected genes (Table 1) were amplified either in monoplex or in multiplex PCR, as previously described.²³ Oligonucleotide sequences and protocol details are available upon request. The electrophoresis profiles of the PCR products obtained with mlh1-3 were compared to the HCT116 reference profiles.

MLH1 protein expression

MLH1 protein expression in HCT116 and mlh1-3 cell lines was detected by Western blot using a rabbit polyclonal antibody raised against MLH1 (PC56, 1 µg/mL, Oncogene Research Products, Cambridge, MA) followed by subsequent incubation with sheep anti-rabbit antibodies conjugated with horseradish peroxidase (Amersham Pharmacia Biotech, Uppsala, Sweden). Analysis of tumour tissues obtained from mice was performed by immunohistochemistry on 4-µm slides incubated with an MLH1-specific mouse monoclonal antibody (dilution 1:400, clone G168-728, BD Biosciences, East Rutherford, NJ) after antigen retrieval with buffer, pH 6.0.

Animal experiments

Locally bred female NOD/SCID mice of 6-8 weeks of age were used for implantation. The animals were maintained under specific pathogen-free conditions, and food and water were supplied *ad libitum*. Housing and all procedures involving animals were conducted in accordance with the European Communities Council Directive (2010/63/UE) for the care and use of animals for experimental procedures and complied with the regulations of the French Ethics Committee in Animal Experiment "Charles Darwin" registered at the "Comité National de Réflexion Ethique sur l'Expérimentation Animale" (Ile-de-France, Paris, no5). Pr Marc Pocard supervised all experiments (agreement no. 75-1229 approved by the "Direction Départementale de la Protection des Populations", Paris, France). All efforts have been made to protect mice from pain, suffering, injury and disease.

Tumour models

Subcutaneous tumours were established by injecting 5×10^6 cells into the flank of 5 mice per cell line. When subcutaneous tumours were exponentially growing, mice were sacrificed to remove the tumours, which were then cut into fragments. The tumour fragments were subsequently implanted subcutaneously into the lateral flank of 5 other mice under inhaled anaesthesia and the incision was closed with a metal wound clip. When tumours reached a sufficient volume, they were resected and cut in $2 \times 2 \times 2$ mm fragments for further intracaecal grafts.

Transplantation procedure

For each cell line, 30 mice were anaesthetized by intraperitoneal injection of 0.2 mL solution of ketamine (100 mg/kg body weight, Ketalar, Parapharm, Chinon, France) and xylazine (40 mg/kg body weight, Rompun, Bayer, La Garenne-Colombes, France). The abdomen was prepared for sterile surgery, as previously described.³⁶ A median incision was performed to exteriorize the colon. A $2 \times 2 \times 2$ mm fragment of solid tumour was then deposited at the surface of the serous membrane of the caecum, fixed with a thread (vicryl 7/0, Ethicon,

France) and covered with 0.5 mL of biological glue (Beriplast, Aventis, Gentilly, France). The caecum was finally replaced in the abdominal cavity and the abdominal wall was closed in two layers: the aponevrose with thread (prolene 5/0, Ethicon, Issy-les-Moulineaux, France) and the skin with a metal wound clip. The group of 30 mice transplanted with either HCT116 or mlh1-3 cells were randomly divided into 2 groups of 15 mice: one in which the tumours were left *in situ* to evaluate the natural tumour history and one that underwent surgical resection; mice were caught randomly and were assigned alternately to each group.

Surgical resection

Surgical resection was performed 10 days after orthotopic transplantation. Mice were anesthetized, abdomen was prepared for sterile surgery and a median incision was made, using the above-described protocol. The colon was exposed after careful dissection and haemostasis of peritoneal adhesions. The caecum was completely resected using a surgical clip, as described.^{35,36} The clip was covered for final haemostasis and asepsis with 0.5 mL of biological glue. The bowel was replaced in the abdominal cavity and the wall was closed in two layers.

Tumour growth and metastasis evaluation

For each animal, an autopsy was performed at day 45 after tumour implantation. Tumour volumes were calculated using the formula $V = a \times b^2 / 2$, where *a* is the length of the tumour (largest diameter) and *b* is the perpendicular width of the tumour (smallest diameter), both measured with a calliper. For each animal, local recurrence and distant metastases (lymph node, liver and lung metastases, peritoneal carcinomatosis) were searched macroscopically at autopsy with histologic confirmation and immunohistochemical labelling of MLH1, as described above. The animals were considered cured if no tumour could be detected in any of the above-mentioned organs when inspected at autopsy.

Statistical analyses

On the basis of a unilateral alpha type one error of 5%, it was necessary to include 10 mice per group to achieve a 90% statistical power if the expected event ratio (local or distant recurrence) was 4, and 8 mice per group if the mean tumour volume ratio was expected to decrease 4-fold upon expression of MLH1. Two-sided Fisher's exact test was used to compare the proportion of mice with recurrence, lymph node metastases, peritoneal carcinomatosis and liver metastases. Tumour volumes were compared using a one-tailed Mann-Whitney U test. Analyses were performed using the Prism 5 software (GraphPad Software Inc, La Jolla, CA).

RESULTS

Feasibility of orthotopic intracaecal xenografts and tumour resection

Among the 60 NOD/SCID mice that had been grafted on the caecum, one died during surgery, one the following day and one at day 8 (1/30 and 2/30 for HCT116 and mlh1-3, respectively), giving a 5% graft-related mortality. Among the 27 animals that did not undergo surgery, tumour graft implantation was successful in 21 animals (10/14 and 11/13, for HCT116 and mlh1-3, respectively), giving an overall tumour take rate of 78%. Among the 30 animals that underwent surgical resection at day 10, five of them (16%) died during the first 8 days after surgical tumour resection (2/15 and 3/15 for HCT116-R and mlh1-3-R, respectively), with one dying the next day.

Microscopy of haematoxylin-eosin (HE) sections showed that macroscopic tumours from both HCT116 and mlh1-3 exhibited invasive growth in the murine caecum towards the intestinal lumen (Figure 1A and B); both HCT116 and mlh1-3 tumours were able to grow through the serosa and invade the muscular layer and the mucosa. Visual examination at autopsy and microscopic examination of HE-stained sections showed that tumours also gave

rise to lymph node metastases (Figure 1C and D), liver metastases in one case (Figure 1E and F), and peritoneal carcinomatosis (Figure 1G and H). HCT116-derived tumours cells were more frequently poorly differentiated, with increased necrosis, than mlh1-3; in addition, HCT116 cells were smaller and less cohesive.

Molecular characteristics of the HCT116 and mlh1-3 cell lines and their counterpart tumours

The expression of MLH1 was investigated in the cell lines and their derived tumours by Western blot and immunohistochemical staining with an anti-MLH1 antibody (Figure 2A-C). As expected, the expression of MLH1 was undetectable in the HCT116 cell line and in the derived HCT116 tumour tissue (Figure 2A and B). In the mlh1-3 cell line obtained by transfecting the MLH1-deficient HCT116 cell line with a wild type *MLH1*-expressing vector, MLH1 was expressed at normal control levels (Figure 2A) and sustained throughout the course of the experiments (not shown). MLH1 expression in grafted mlh1-3 tumours was maintained in spite of discontinued antibiotic selection pressure for the *in vivo* experiments (Figure 2C). Interestingly, HE staining showed that tumours derived from HCT116 or mlh1-3 cells displayed similar morphological features (Figure 2B and C). Figure 2 shows the MSI phenotype of the HCT116 and mlh1-3 cell lines, as well as their corresponding tumour tissues, determined using 3 highly polymorphic dinucleotide microsatellite markers. As expected, the HCT116 cell line (Figure 2D) displayed a typical high MSI profile, with numerous peaks corresponding to the amplification of alleles derived through deletion or insertion of CA motifs in the parental alleles. Conversely, no microsatellite instability could be detected in the mlh1-3 cell line (Figure 2E), or its derived subcutaneous (Figure 2F) or intracaecal (Figure 2G) tumour tissues obtained from the 23 mice analysed at autopsy (Figure 2 and data not shown).

We further compared the mutational status of 26 genes harbouring a mononucleotide repeat in HCT116 and mlh1-3 cells (Table 1). No difference was found between the two cell lines: the coding repeated sequences were wild-type in sixteen genes, while seven genes

displayed a monoallelic 1 bp deletion (*BAX*, *MBD4*, *POLD3*, *RAD50*, *RECQL*, *TOPBP1* and *TOPORS*) together with a wild-type allele; the other three genes had 1- or 2-bp biallelic deletions (*MRE11*, *MSH3* and *TGFBR2*) (Table 1).

DNA fingerprinting of the two cell lines and their derived intracaecal tumours was performed using 8 STR markers that enables a 1 in 10^8 discrimination rate for unrelated individuals (Supporting Information Table 1). Alleles are referred to by their number of repeats determined using a reference panel of six cell lines of known genotype. Profiles were identical for all samples tested confirming that mlh1-3 and intracaecal tumours derived from HCT116. Yet, there were minor differences between the HCT116 and mlh1-3 profiles and the one available at the ATCC website. The first difference was located at the vWA marker and consisted of an addition of a single nucleotide that was detected in HCT116 and its mlh1-3 derived cell line, indicating that this mutation occurred in the HCT116 parental cell line before it was complemented with the MLH1-expressing vector; this observation was not unexpected since HCT116 is deficient in mismatch repair. The other difference is that the intensity of the Y-chromosome-specific amelogenin allele is below expected suggesting that part of the cells lost their Y-chromosome, or that a 6-bp deletion occurred in the Y-chromosome, generating a size that is identical to that of the X-chromosome.

Spontaneous evolution of the HCT116 and mlh1-3 intracaecal tumour xenografts

As shown in Table 2 and Figure 3, the mean tumour volume in the group of mice implanted with mlh1-3-derived tumours was significantly smaller than in those with HCT116 ($P = .001$), despite large variations within each group. Lymph node metastases and peritoneal carcinomatosis occurred significantly more often in the group of mice grafted with HCT116, compared to the group of mlh1-3 tumour-bearing animals ($P = .007$ and $P = .035$, respectively) (Table 2). Mice grafted with mlh1-3 tumours did not develop peritoneal carcinomatosis or liver metastasis; the only liver metastasis was observed in the group of mice grafted with the HCT116 tumour (Table 2).

Evolution of the HCT116 and mlh1-3 intracaecal tumour xenografts after surgical resection

In order to study tumour evolution after curative surgery, HCT116 and mlh1-3 intracaecal tumour xenografts were resected at day 10. The rate of local recurrence after surgical resection did not differ significantly between the two groups, varying from 38% (5/13) for HCT116-R to 25% (3/12) for mlh1-3-R (Table 2); tumour volumes varied widely in both groups and were not significantly different. Lymph node metastases occurred only in the group of mice initially implanted with the HCT116 tumour, but the difference failed to reach the level of significance ($P = .096$). Moreover, a single mouse of the mlh1-3 group displayed peritoneal carcinomatosis, whereas it occurred at a significantly higher frequency in mice initially grafted with the HCT116 tumour ($P = .011$). No liver metastases were detected in either group. The rate of cure was significantly higher in the mlh1-3 group in which only 3/12 animals relapsed, while 9/13 animals of the HCT116 group relapsed ($P = .047$) (Table 2).

DISCUSSION

CRCs are characterized by accumulation of genetic alterations that drive tumour progression from non-invasive adenomas to invasive adenocarcinomas. High-throughput arrays have been extensively used to uncover transcriptional gene expression or genomic aberration profiles in primary CRCs that might predict prognosis of patients with stage II⁴³⁻⁴⁵ and/or stage III^{46,47} CRC, or the site of metastases.^{48,49} Despite considerable efforts, no signature has been translated into the clinical management of patients due to low prediction accuracy.⁵⁰

Patient-derived xenograft models have been developed to address specifically the role of putative oncogenes or tumour suppressor genes in CRC progression, or to predict drug sensitivity.⁵¹⁻⁵⁵ For instance, orthotopic xenograft tumour models in immunodeficient mice have been successfully used to assess the function of TP53 and E-cadherin,³⁹ and more

recently that of TGF β RII⁴¹ in CRC progression. Interestingly, intracaecal xenografted tumours may be subsequently resected, mimicking the surgical resection of primary CRC in humans, thus providing an opportunity to evaluate the benefit of surgery in well-defined tumour models.

Our orthotopic xenograft model recapitulates all aspects of human CRC progression, i.e. lymph node invasion, peritoneal carcinomatosis, liver metastasis and local recurrence after tumour surgery, with the exception of lung metastasis. Importantly, we were able to show that the *MLH1* cDNA remained stably expressed throughout the experiments, even when selection pressure by hygromycin had been removed for *in vivo* experiments. All cell lines and tumours also shared the spectrum of mutations in the 26 mononucleotide coding repeats analysed and an identical profile at the 8 tetranucleotide STR loci, supporting that mlh1-3 is genetically close to the parental HCT116. In addition, all cell lines gave rise to tumours displaying similar morphological features. Thus, our model based on the isogenic HCT116 and mlh1-3 cell lines seems to be appropriate to investigate the impact of MLH1 expression on tumour progression independently of the MSI-driven mutations that previously arose in target genes.

We here show that the growth of tumours derived from the MLH1-complemented mlh1-3 cell line was slower compared to HCT116, a finding that is in keeping with the fact that MSI CRC tend to be larger than MSS CRC, possibly reflecting the role of MLH1 in cell cycle regulation and apoptosis.⁵⁶ Interestingly, restoring MLH1 expression significantly decreased the rate of peritoneal carcinomatosis regardless of whether the tumour was resected or not. This is in line with a recent publication reporting that as many as 25% of the tumours arising in patients undergoing cytoreductive surgery for peritoneal carcinomatosis from CRC displayed MSI, a frequency that is higher than in unselected stage IV CRC, suggesting that MSI might favour peritoneal metastases.⁵⁷ The decreased incidence of lymph node invasion was statistically significant when comparing mice that did not undergo surgery, but not for mice that underwent tumour resection, possibly due to lack of power since the number of mice was

rather low. Yet, ethical considerations led us to reduce the number of animals used to achieve our aim, which was to document substantial differences in tumour progression.

MSI CRCs are considered to have a better prognosis compared to MSS CRCs, but the underlying molecular alterations have not been identified yet.⁵⁸ In particular, the impact of MMR deficiency *per se* on tumour progression, independently of MSI-driven mutations, remained to be investigated. The possibility that mutations in *TGFBR2*, one of the genes most frequently mutated in MSI CRC, represent prognostic biomarkers has been investigated in several studies with conflicting results.⁵⁹⁻⁶¹ Interestingly, a recent study reported that reexpressing *TGFBR2* in the HCT116 cell line that carries a biallelic *TGFBR2* frameshift mutation, increased cell survival and motility *in vitro* and enhanced their *in vivo* metastatic potential in an orthotopic model in nude mice, indicating that TGF β signalling may indeed modulate the metastatic potential of MSI CRC.⁴¹ Experiments in which expression of wild-type *MLH1* is obtained by introducing a normal human chromosome 3 also provide a normal *TGFBR2* allele, because the *TGFBR2* gene is located in the close vicinity of *MLH1* on chromosome 3,⁶² thus hampering the investigation of the respective contribution of *MLH1* and *TGFBR2* *per se*. The HCT116 / *mlh1*-3 model that we established overcomes this problem since *MLH1* is restored by transfecting a vector expressing the wild-type *MLH1* cDNA, which does not change the *TGFBR2* status of HCT116 cells.⁴² Our results show that the clinical status of mice xenografted with the *MLH1*-expressing tumour was significantly improved compared to those with the parental HCT116-derived tumour, underlying the role of *MLH1* deficiency in itself in tumour progression. Expression of *MLH1* was notably associated with a significantly lower chance of recurrence after curative surgery, as well as a decreased incidence of lymph node invasion and peritoneal carcinomatosis in animals, regardless of whether the tumour was resected or left *in situ*.

In our xenograft experiments, the absence of *MLH1* expression tended to be associated with a worse evolution, while patients with MSI CRC had a better stage-adjusted prognosis than those with CRC displaying chromosome instability.^{7,8} The major distinction between these apparently contradictory findings is that, in humans, the differences between MSI and non-

MSI tumours reside not only in the fact that one of the MMR genes (most often *MLH1* or *MSH2*) is not functional, but also in the genome-wide accumulation of *de novo* mutations due to inefficient post-replicative repair, while in the animal model that we used, the only difference that we could detect was *MLH1* expression. Although such animal models may help deciphering the impact of specific genetic alterations, such as *MLH1* deficiency, on cancer progression, there are several limitations. Tumour xenograft models are not well-suited to study interactions between cancer cells and tumour environment because interspecies molecular communications, including ligand-receptor interactions, are likely to differ.⁵⁴ In addition, being severely immuno-compromised, NOD/SCID mice obviate assessing the well-recognized role of the immune system, in the metastatic process in CRC.⁶³ Addressing this question would be extremely hard as reconstitution of a human immune system in immunodeficient mice should be done with patient-matched immune cells, which greatly limits the feasibility.

ACKNOWLEDGMENTS

FIGURES LEGENDS

FIGURE 1. Examples of tumours and metastases obtained with the HCT116 cell line. Macroscopic examination and hematoxylin-eosin-safran stained slides of tumours developing in the caecum (A and B), lymph node (C and D), liver (E and F) and peritoneum (G and H).

FIGURE 2. MLH1 expression and MSI phenotyping in HCT116 and mlh1-3 cell lines, and their derived xenografted tumours. MLH1 expression HCT116 and mlh1-3 cell lines was detected by Western blot (A) and compared to the MSS CRC HT29 cell line, used as a positive control; GAPDH was used as a loading control. MLH1 expression in HCT116 (B) and mlh1-3 (C) xenografted tumours was assessed by IHC; positive cells exhibit a strong nuclear staining. HE staining of small areas of these samples obtained at the same magnification is shown in inlays (B and C). Amplification profiles of three CAn dinucleotide polymorphic markers are shown for the HCT116 (D) and mlh1-3 (E) cell lines, and the mlh1-3-derived subcutaneous (sc) (F) and intracaecal (ic) (G) tumours. Multiplex PCR products corresponding to *D5S107* (6-FAM-labelled, in blue), *D18S1127* (NED-labeled, in black), and *D17S1791* (NED-labeled, in black) co-migrated with the ROX-labelled 400 HD size markers ranging from 50 to 400 bp (in red), used to calculate the size of the PCR fragments. The x-axis represents the size of the amplicons in bp; the amplicon sizes range from 133 to 155 pb for *D5S107*, from 178 to 204 bp *D18S1127* and from 270 to 290 bp for *D17S1791*. The chromatogram pattern obtained for HCT116 (D) shows additional peaks typical for MSI tumours, compared to MLH1-corrected mlh1-3 cell line (E); patterns obtained with subcutaneous (F) and intracaecal (G) tumours were identical to that of mlh1-3 cell line; samples are homozygous for *D5S107* and heterozygous for *D18S1127* and *D17S1791* (parental alleles are indicated by arrows).

FIGURE 3. Growth of intracaecal HCT116 and mlh1-3 derived tumours. Volumes of intracaecal tumours derived from HCT116 (HCT116 ■) and mlh1-3 (mlh1-3 ●) when left *in*

situ or of local recurrences arising after surgical resection (HCT116-R □ and mlh1-3-R ○) were measured at autopsy. Tumour volumes were compared using a one-tailed Mann-Whitney U test. The difference was statistically significant for tumours left *in situ* ($P = .001$), but not after surgical resection ($P = .125$).

<i>MBD4</i>	8930	A10	3q21-q22	-1/wt	-1/wt
<i>MRE11A</i>	4361	T11	11q21	-2/-1	-2/-1
<i>MSH3</i>	4437	A8	5q11-q12	-1	-1
<i>MSH6</i>	2956	C8	2p16	wt	wt
<i>POLA1</i>	5422	A8	Xp22.1-p21.3	wt	wt
<i>POLD3</i>	10714	A9	11q14	-1/wt	-1/wt
<i>PRKDC</i>	5591	A10	8q11	wt	wt
<i>RAD50</i>	10111	A9	5q31	-1/wt	-1/wt
<i>RBBP8</i>	5932	A9	18q11.2	wt	wt
<i>RECQL</i>	5965	A9	12p12	-1/wt	-1/wt
<i>RIF1</i>	55183	A8	2q23.3	wt	wt
<i>SMC1B</i>	27127	A8	22q13.21	wt	wt
<i>TCF7L2</i>	6934	A9	10q25.3	wt	wt
<i>TGFBR2</i>	7048	A10	3p22	-1	-1
<i>TOPBP1</i>	11073	A8	3q22.1	-1/wt	-1/wt
<i>TOPORS</i>	10210	A8	9p21	-1/wt	-1/wt
<i>WRN</i>	7486	A8	8p12-p11.2	wt	wt
<i>XRCC2</i>	7516	T8	7q36.1	wt	wt

Gene symbols are according to HUGO gene nomenclature committee. Gene ID is from the NCBI Entrez gene database. The alleles detected were either wild-type (wt), or carry a 1 bp or a 2 bp deletion (noted as "-1" or "-2", respectively); wt : only wild-type alleles were detected; -1/wt : both wt alleles and alleles carrying a 1 bp deletion were detected; -1: only alleles with a 1 bp deletion were detected; -2/-1: alleles carrying a 2 bp deletion and alleles with a 1 bp deletion were detected. All repeats are located in the coding sequences, except for *MRE11A* whose T11 repeat is located in an intron and whose shortening induces exon skipping; thus, a 1 or 2 bp deletion results in a frameshift mutation.

TABLE 2. Clinical status of mice with intracaecal HCT116 and mlh1-3 tumour xenografts left *in situ* or after surgical resection

	Spontaneous tumour evolution			Evolution after tumour resection		
	HCT116	mlh1-3	<i>P</i>	HCT116-R	mlh1-3-R	<i>P</i>
Number of mice	10	11		13	12	
Tumour volume (mm³)						
Mean	1483	431	.001	686	1787	.125
SEM	242	215		526	843	
Recurrence after surgery				9	3	.047
Local recurrence after surgery				5	3	.673
Distant recurrence	7	1	.007	8	1	.011
Lymph node metastases	7	1	.007	4	0	.096
Liver metastases	1	0	.476	0	0	na ^a
Peritoneal carcinomatosis	4	0	.035	8	1	.011

Fifteen mice were initially grafted in each group; the number of mice analysed decreased due to early death after tumour graft (n = 3) or surgical resection (n = 5), and to the absence of tumour take (n = 6). The volumes of tumours growing on the caecum were compared using a one-tailed Mann-Whitney U test. To compare the number of mice with recurrence, lymph node metastases, peritoneal carcinomatosis and liver metastases, *P* values were calculated using two-sided Fisher's exact tests.

^a not analyzed (na): no *P* value could be calculated to compare the number of mice with liver metastases after tumour resection since there was no event in either group.

Supporting Information Table 1. DNA fingerprinting of HCT116 and mlh1-3 cell lines and their derived intracaecal tumours

		<i>D5S818</i>	<i>D7S820</i>	<i>D13S317</i>	<i>D16S539</i>	<i>Amelogenin</i>	<i>CSF1PO</i>	<i>THO1</i>	<i>TPOX</i>	<i>vWA</i>
HCT116	ATCC	10,11	11,12	10,12	11,13	X,Y	7,10	8,9	8,9	17,22
HCT116	<i>In vitro</i> cell line	10,11	11,12	10,12	11,13	X (Y)	7,10	8,9	8,9	17,22.1
	Caecum graft, P5	10,11	11,12	10,12	11,13	X	7,10	8,9	8,9	17,22.1
mlh1-3	<i>In vitro</i> cell line	10,11	11,12	10,12	11,13	X	7,10	8,9	8,9	17,22.1
	Caecum graft, P6	10,11	11,12	10,12	11,13	X	7,10	8,9	8,9	17,22.1

Profiling was performed using the eight short tandem repeat (STR) markers recommended by the American Type Cell Culture (ATCC), which enables a 1 in 10⁸ discrimination rate for unrelated individuals. Multiplex PCR was carried and analyzed as in Figure 2D-G. Alleles are referred to by their number of repeats defined using a panel of six cell lines used as reference. The Y chromosome specific amelogenin allele shown in parentheses indicate that its intensity is far below expected. The size of the vWA 22.1 allele is 1 bp longer than the allele with 22 repeats reported for the HCT116 cell line on the ATCC website.
