ABSTRACT

In this work we present a detailed surface science characterization of L-Aspartic acid adsorption on a Cu(110) surface. Aspartic acid is one of the main components of the tri-peptide RGD (arginine-glycine-aspartic acid). We replaced the traditional sublimation method to obtain molecular films by dosing aspartic acid directly from an aqueous solution through an Electrospray Ionization (ESI) device. X-ray Photoelectron Spectroscopy (XPS) and Polarization Modulation Reflection Absorption Infra Red Spectroscopy (PM-RAIRS) evidenced different

1
2
3 adsorption states ranging from sub-monolayer regime up to multilayers. Molecules-substrate
4 interactions guide the creation of the pattern observed in the sub-monolayer, but molecule-
5 molecule interactions are prevailing from a certain coverage stage, promoting the overlayer
6 growth while leaving exposed areas of bare copper. This is evidenced by Scanning Tunneling
7 Microscopy (STM) results, showing that single aspartic acid molecules self-organize in a 2D
8 chiral network at low coverage and start originating new molecular layers even before a saturated
9 monolayer has been reached.

22 INTRODUCTION

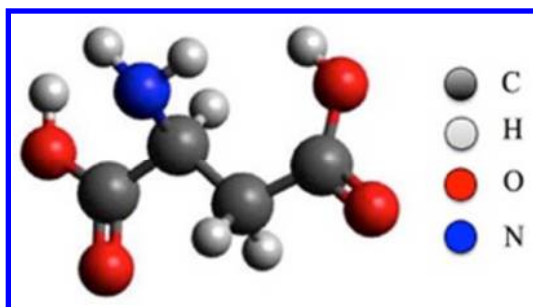

23
24 A better knowledge and control of biomolecule-metal interactions is a central issue for the
25 rational design of biocompatible and/or protein-resistant materials. Fundamental research is
26 always at the intermediate position between a fully understanding of small molecule adsorption
27 on well-defined surfaces (“ideal” surface science approach) and “post mortem” characterization
28 of real biological systems (“real” approach). In this context, we put our effort on the study of the
29 adsorption of small biomolecules, namely amino acids and small di- or tri-peptides, on metallic
30 single crystal surfaces, most often by applying a surface science approach.
31

33
34
35
36
37
38
39
40

41 We have recently shown that molecules dosed via an electrospray ionization (ESI) device are
42 adsorbed intact and in a chemical state close to that in solution.^{1,2} Compared to the traditional
43 Knudsen cells, ESI allows an adsorption from an aqueous solution at room temperature; high
44 sublimation temperatures are thus avoided and molecular films of delicate biomolecules can be
45 obtained without any molecular damage. Our next objective is to unravel the interaction
46 modalities of more relevant peptides, like RGD, which plays a determining role in the context of
47 biotechnologies for its capacity to promote cell adhesion or other peptide sequences for specific

1
2
3 molecular recognition or cell interactions on metallic or oxidized surfaces³. RGD is currently
4 employed for biomaterials functionalization and knowledge of RGD adsorption mechanisms on
5 different surfaces is of paramount importance for its implementation. The tri-peptide RGD is
6 constituted of three amino acids, namely arginine, glycine and aspartic acid (ASP). Arginine and
7 ASP, differently from glycine,^{4,5,6,7,8,9} have not given rise to extended investigations of their
8 interaction with a metal surface.
9

10
11 As a first step in the characterization of RGD interaction with a copper surface, we studied
12 ASP adsorption on a Cu(110) surface. Moreover, considering that RGD, a rather heavy tri-
13 peptide, will not be easily sublimated in the UHV chamber, an ESI device will probably be
14 necessary to introduce RGD with no damage. Therefore, we have already used the ESI device for
15 ASP in order to keep similar evaporation conditions.
16

17
18 ASP, C₄H₇NO₄ (Figure 1), is mostly known for being one of the main ingredients of the
19 artificial sweetener *aspartame*, together with L-phenylalanine. What is maybe less known is that
20 is one of the most abundant amino acids in nature, it has fundamental biological and
21 biomedical/biotechnological functions^{10, 11, 12, 13, 14, 15} and, last but not the least, is the C-ter end of
22 RGD.

53

54
55 From a chemical point of view, ASP contains an amine group and two distinct carboxylic acids
56 at its two extremities. It has been extensively studied, theoretically and experimentally, on
57
58
59
60

1
2
3 oxyhydroxide surfaces, like TiO_2 ^{16, 17} and Al_2O_3 ,¹⁸ in view of possible applications in various
4 fields of interest, ranging from biomedical devices to earth science and astrobiology. Most of
5 these studies were performed *ex-situ*, by coating aspartic acid in solutions on the substrates,
6 followed by sample characterization.
7

8
9
10
11
12
13 Studies of ASP on metallic substrates and in ultra-high vacuum (UHV) conditions are quite
14 rare. ASP has been adsorbed on Ni(111) surfaces, from solution¹⁹ and by sublimation,²⁰ as a
15 surface chiral modifier to investigate the enantioselective hydrogenation of β – ketoesters. More
16 recently, Gellman and co-workers have studied ASP films evaporated (in racemic mixture or as
17 pure D or L enantiomers) in UHV conditions, to characterize the enantiomer nature of ASP
18 molecules on chiral and achiral copper surfaces.^{21, 22, 23, 24, 25} All these studies have in common
19 the conclusion that ASP chemical form after adsorption on a surface depends on the film
20 coverage. However, this form is different according to the substrate. On Ni surfaces, ASP is in its
21 zwitterionic ($\text{COO}^-/\text{NH}_3^+$) form at lower coverages, and in its anionic (COO^-/NH_2) form at high
22 coverages.²⁰ On Cu surfaces, ASP is found with two COO^- groups and a neutral (NH_2) amine
23 group for lower coverage and in its zwitterionic form for higher coverage.²⁵ The doubly-
24 deprotonated carboxylic groups and the neutral amine group of the lower coverage are
25 considered the responsible for the ASP anchorage on the surface.

44 This work aims at studying the adsorption mechanisms of L-ASP after deposition by ESI on
45 Cu(110) surfaces. The chemical state and the anchoring points of the molecules on the surface,
46 deduced through X-ray Photoelectron Spectroscopy (XPS) and Polarization Modulation Infrared
47 Reflection Absorption Spectroscopy (PM-RAIRS) revealed, also in this case, changes in the
48 chemical state, charge and configuration of ASP molecules, with the coverage. Scanning
49 Tunneling Microscopy (STM) furnished complementary information about the layer structure,

10 11 12 13 **EXPERIMENTAL SECTION**

14
15 All measurements were performed in UHV conditions, *i.e.* with a base pressure better than
16
17 1×10^{-10} mbar, with the sample kept at room temperature. PM-RAIRS and XPS measurements
18
19 were realized *in situ*. STM images were acquired after dosing using a different experimental
20
21 equipment.
22
23

24
25 **Materials.** Before ASP adsorption, the Cu(110) crystal (Surface Preparation Laboratory, The
26
27 Netherlands, purity of 99.99% (4N) and alignment accuracies of 0.1°) was prepared for the
28
29 experiments through several cycles of Ar^+ sputtering (500 eV, $P_{\text{Ar}}=3 \times 10^{-6}$ mbar) and annealing at
30
31 850 K. XPS and LEED (Low Energy Electron Diffraction) were used to check surface
32
33 cleanliness and reconstruction. L-ASP was purchased by Fluka (99%) and used without further
34
35 purification.
36
37

38
39 **Dosing.** ASP adsorption has been realized from a 1 mM solution of ASP in a methanol/water
40
41 75:25 ratio by means of an ESI device. Explanations on ESI mode and principles of operation
42
43 can be found elsewhere.^{1,2}Error! Bookmark not defined. Dosing of 2, 5 and 7 minutes for XPS and 2 and
44
45 5 minutes for STM were used to obtain different ASP coverage. The pressure during the dosing
46
47 varied in the range 1×10^{-7} to 5×10^{-7} , with a base pressure of 7×10^{-8} after opening the gate valve
48
49 between the ESI vessel and the experimental chamber. A positive voltage of 1.5 kV was applied,
50
51 with ASP gas phase molecules nominally in their cationic state, *i.e.* $\text{COOH}/\text{NH}_3^+$.

Thickness evaluation. The thickness d of the obtained molecular layer could be estimated by means of the intensities ratio IC_{1s}/IC_{Cu2p} of C1s and Cu2p XPS spectra, related by the formula:

$$\frac{IC_{1s}}{IC_{Cu2p}} = \frac{T_{C_{1s}}}{T_{Cu_{2p}}} \frac{\sigma_{C_{1s}}}{\sigma_{Cu_{2p}}} \frac{\lambda_{C_{1s}}^{ad} C_{C_{1s}}^{ad} \left[1 - \exp\left(\frac{-d}{\lambda_{C_{1s}}^{ad} \cos\theta}\right) \right]}{\lambda_{Cu_{2p}}^{su} C_{Cu_{2p}}^{su} \exp\left(\frac{-d}{\lambda_{Cu_{2p}}^{ad} \cos\theta}\right)} \quad [1]$$

where $\cos\theta$ is 1 because the photoelectron collection angle θ is equal to zero. $T_{C_{1s}}$ and $T_{Cu_{2p}}$ are the relative sensitivity factors of C and Cu, respectively, provided by the spectrometer manufacturer. The Scofield photoionization cross sections σ are 1 for C 1s and 2.48 for Cu 2p. The superscripts *ad* and *su* designate the adsorbed layer and the copper substrate, respectively. C_x^y represents the concentration of the element x in the matrix y . The electron inelastic mean free paths λ were calculated using the Quases program based on the TPP2M formula.²⁶ For more details on equation [1], see Supp. Info section.

PM-RAIRS. Spectra were recorded using a Nicolet 5700 spectrometer equipped with a nitrogen-cooled MCT wide-band detector. A ZnSe grid polarizer and ZnSe photoelastic modulator to modulate the incident beam between p and s polarization were placed prior to the sample. The spectrometer was interfaced to the UHV chamber via ZnSe windows. The reflected light was focused onto the detector at an optimal incident angle of 85°. All spectra were obtained after 1024 scans with a resolution of 8 cm⁻¹.

XPS. Photoemission analysis was performed using a SPECS (Phoibos 100 1D Delay Line Detector) hemispherical analyzer and a monochromatized aluminum K_α X-ray source ($h\nu = 1486.6$ eV). The acquired spectra were calibrated according to the Cu Fermi level. The experimental uncertainty on the position in binding energy of the XPS peaks is 0.1 eV.

1
2
3 **STM.** STM experiments were conducted in an Omicron Vakuumphysik XA VT-STM
4 chamber with facilities for STM, LEED and sample cleaning. All STM images were acquired in
5 constant current mode. The STM scanner was calibrated using the Cu(110)-O-(2×1)
6 missing/added rows (interspacing distance = 0.51 nm).

12 13 14 15 **RESULTS AND DISCUSSION**

16
17 PM-RAIRS spectra obtained after a 2, 5 and 7 minutes dosing by ESI are shown in Figure 2a,
18 together with the peak assignment (Figure 2b) in agreement with previous ASP infrared studies²⁷
19 and with the infrared analysis of ASP solutions at different pHs (see the Supporting Information
20 section, Figure S1). One can notice three main features at 1427 cm⁻¹, 1391 cm⁻¹ and 1352 cm⁻¹,
21 present on the PM-RAIRS spectra at all examined coverages. The sharp bands at 1427 cm⁻¹ and
22 1391 cm⁻¹ are attributed to the symmetric stretching vibrations of, respectively, the α -carboxylate
23 (closer to the amine group) and the distal carboxylate functionalities (Figure S1). The not
24 symmetric position of the amine group in the molecule breaks the degeneracy of the two
25 otherwise equivalent COO⁻ groups and leads to two distinguishable contributions. The observed
26 vibrations also furnish a direct evidence of the carboxylic acids deprotonation. As already
27 reported for other copper surfaces,²⁸ the hydrogen atoms released by protonation processes
28 undergo recombinative desorption as hydrogen molecules

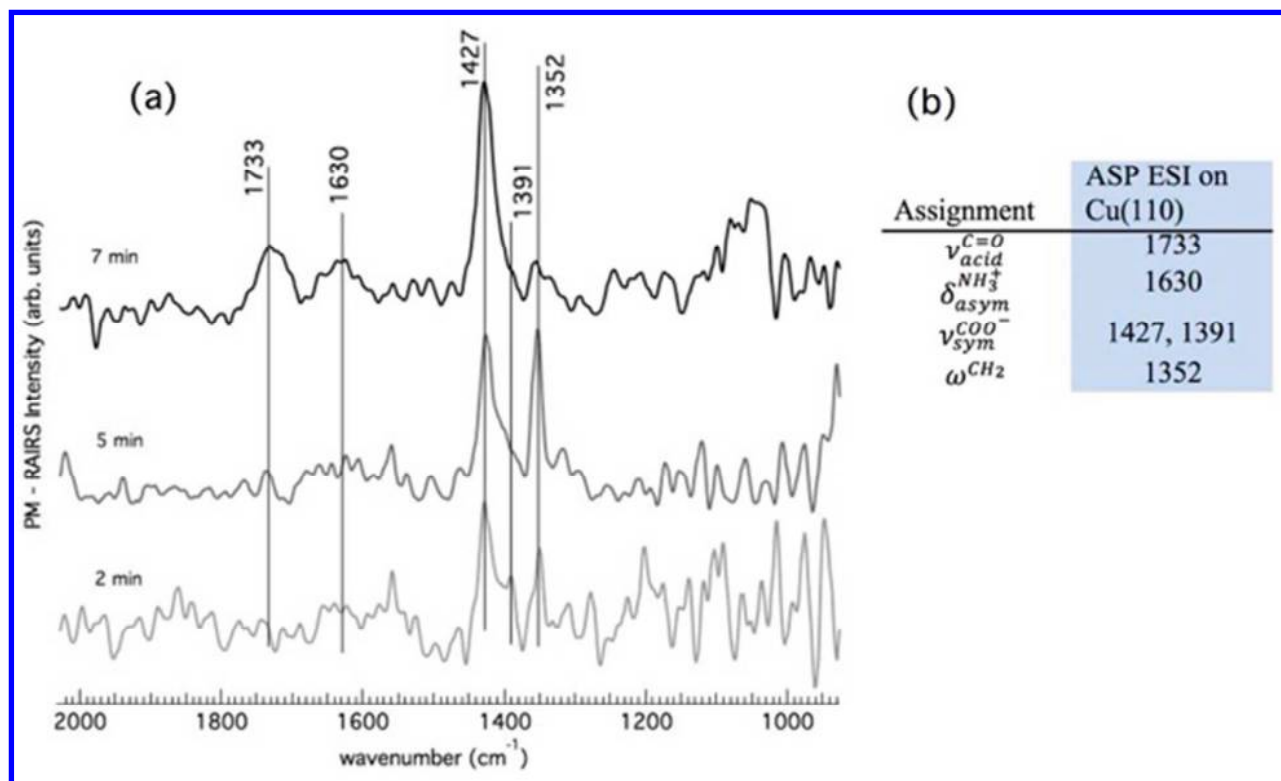

Figure 2. (a) PM-RAIRS spectra obtained after a 2, 5 and 7 minutes dosing by ESI; (b) Peak assignment table.

The third rather intense band at 1352 cm^{-1} can be ascribed to the CH_2 wagging mode.²⁰ Increasing the molecular coverage on the substrate, one observes two other bands growing. The $\text{C}=\text{O}$ stretching mode and the NH_3^+ asymmetric deformations, visible in the 7 minutes adsorption spectrum in Figure 2a, are responsible for the broad features at 1733 cm^{-1} and 1630 cm^{-1} , respectively. Additional information concerning the (protonated or not) nature of the amino group will be given by analyzing the XPS data.

The N1s and O1s XPS spectra obtained at the three investigated dosing times are shown in Figure 3. The spectra and the subsequent analysis are in perfect agreement with a previous study of ASP sublimated on Cu(110),²⁵ confirming once again that ESI is as accurate and reproducible, in term of sample preparation methods, as traditional sublimation. For nitrogen, Figure 3b, in the 2 minutes adsorption spectrum, the Binding Energy (BE) of the N1s peak at 399.9 eV is

characteristic of the neutral amino NH_2 group; a peak at higher binding energy, 402.1 eV, is visible and intense after longer times of exposure (5 and 7 minutes), attributed to the protonated NH_3^+ groups.^{25,29 30, 31,32}

Figure 3. Evolution of ASP O1s (a) and N1s (b) XPS peaks, for increasing molecular coverage. The fitting procedure to disentangle the contributions of the different species to the core level spectra is also shown.

At the same time, the presence of the NH_2 peak, alone, suggests that the initial interaction of the molecule with the surface induces a deprotonation of all NH_3^+ groups existing in the gas phase. Consistently, for oxygen (Figure 3a), a unique O1s peak at 531.7 eV, ascribed to the COO^- group oxygen, indicates a deprotonation of COOH groups, confirming the interaction of the

1
2
3 carboxylate groups with the surface, as deduced from infrared data (Figure 2). One has to point
4
5 out that the cationic state of ASP molecules obtained through ESI is an assumption based on the
6
7 ESI working principles. In fact, in lacking of gas phase measurements on the ESI beam, we
8
9 cannot exclude the possibility that molecules are in a different state. In particular, the obtained
10
11 data would be also consistent with neutral (COOH/NH₂) ASP molecules arriving on the surface.
12
13 For the 2 minutes results, this would simply imply that no deprotonation occurs in the amine
14
15 group, while keeping the same interaction mechanisms for the carboxylic groups. After 5 minute
16
17 dosing, the N 1s spectrum displays two peaks, indicating that the NH₃⁺ groups now exist in the
18
19 adsorbed molecules. Together with this change in the N1s peak, two peaks on the high binding
20
21 energy tail of the COO⁻ peak start to be visible on the O1s spectrum, at 532.9 and 533.6 eV
22
23 respectively. These are the contributions from C=O and C-OH oxygen atoms,^{33,34} suggesting the
24
25 presence of COOH. Note that these two contributions have equal intensities, and their relative
26
27 intensities increase from 5 to 7 minutes (12 % to 16 % of the total O1s intensity). The C 1s
28
29 spectra for the three dosing times, shown in the Supporting Information section (Figure S2), are
30
31 in agreement with O1s data, confirming COOH complete deprotonation for low coverage and
32
33 COOH neutral state, coexisting with some COO⁻, for higher coverages. Eventually, the values of
34
35 the average coverage values, calculated from the attenuation of the copper signal (Equation 1),
36
37 lead to the following numbers: 3.2 Å, 6.7 Å and 10 Å after 2, 5 and 7 minutes of dosing,
38
39 respectively. Estimating a maximum size for ASP molecules of 5 Å (maximum gas phase
40
41 elongation), one may think that after 2 minutes of exposures, only a fraction of monolayer is on
42
43 the surface whilst multilayer starts to grow after 5 minutes of exposure. This will be later
44
45 confirmed by STM images.

1
2
3 The appearance of the NH_3^+ , C-OH and C=O peaks after 5 minute dosing is in agreement with
4 the building of multilayers where molecules do not interact directly with the surface, thus do not
5 undergo a deprotonation of COOH and NH_3^+ groups. Alternatively, in the presence of neutral gas
6 phase molecules, the 5 and 7 minutes results would infer the creation of a zwitterionic network in
7 the multilayer, with one deprotonated carboxylic group in interaction with the positively charged
8 amine group and the second carboxylic group still in its neutral state. Another possibility would
9 be the NH_2 group of the monolayer turning into NH_3^+ and interacting with a COO^- group of the
10 second layer. Both situations are consistent with the high binding energy contributions observed
11 in O, N and C 1s spectra for higher coverages. The process determining the state of the amine
12 (carboxylic) group would not be an actual protonation (deprotonation) but a delocalization of the
13 proton, favored by the amine (acid) nature of the functional group.

29 Gathering all the information obtained so far and considering the strict RAIRS dipole selection
30 rules, which allow observing only vibrational modes with a dynamic dipole moment non-parallel
31 to the surface,³⁵ we can deduce some characteristics of the geometries of adsorbed ASP
32 molecules depending on the coverage. In the submonolayer regime (2 minutes dosing), the
33 intense symmetric COO^- band and the almost absence of absorption at ca 1600 cm^{-1} suggest that
34 the four oxygen atoms from the COO^- groups are anchored to the surface in a bidentate
35 configuration. A similar geometry was observed for bitartrate³⁶ and bisuccinate³⁷ on Cu(110) and
36 it is also in agreement with the geometry proposed in previous ASP studies.^{24,25} Besides that,
37 looking at the different intensities of the carboxylate bands at 1391 and 1427 cm^{-1} (Figure 2a),
38 we can say that the OCO planes positions, even if close to be normal to the surface plane, are
39 slightly different, with the distal carboxylate plane less perpendicular than the α -carboxylate
40 plane with respect to the surface and thus less contributing to the infrared spectral intensity.

1
2
3 Differently from studies from Gellman's group,^{24,25} we hypothesize that the NH₂ amine group is
4 not interacting with the surface. In fact, since no contribution from the NH₂ group is visible in
5 corresponding infrared data, we deduce that, at low coverage, its plane is parallel, or almost
6 parallel, to the surface. Besides, N1s 2 minutes spectrum (Figure 3a) denotes the absence of
7 interactions between NH₂ and Cu, otherwise a peak at lower binding energies would have been
8 visible, due to hydrogen bonds, -N-H—Cu, between the amine group and the Cu surface, as
9 already been observed in similar studied on copper¹ and on gold surfaces.^{30,38} After 5 minutes
10 adsorption the α -carboxylate band increases, while the distal carboxylate band remains constant
11 (Figure 2a), thus suggesting a slight reorientation of the former carboxylate in a more
12 perpendicular position and of the latter carboxylate in a more parallel position with respect to the
13 substrate. Finally, the appearance of the C=O stretching mode and of the NH₃⁺ asymmetric
14 deformations bands and the decreasing of the CH₂ wagging band intensity in the 7 minutes
15 adsorption infrared spectrum suggests that, once the multilayer regime is reached, molecules are
16 found in various orientations, some letting COOH and NH₃⁺ planes more perpendicular and CH₂
17 planes more parallel to the surface. Changes in molecular arrangement when the coverage
18 increases is a commonly observed phenomenon, already encountered, for alanine,³⁹ tartaric
19 acid,³⁶ lysine⁴⁰ and methionine³¹ on Cu(110).

41
42
43
44 Figure 4 presents the STM images corresponding to a submonolayer of ASP on the Cu(110)
45 surface; one can see on Figure 4a that ASP tends to originate organized structures forming
46 islands on the surface. A closer look into one of the islands (Figure 4b) reveals that those are
47 made of "bilobate" elements. Tracing several line profiles longitudinally along the elements (line
48 profile 1, Figure 4c, we discovered that the two lobes are (3.7 ± 0.4) Å apart and one is at a
49 slightly different z position with respect to the other.
50
51
52
53
54
55
56
57
58
59
60

1
2
3 As pointed out from infrared results, OCO planes of the two ASP carboxylate groups are
4 characterized by a different angle with respect the substrate, being the α -carboxylate $^-OOC-NH_2$
5 group more perpendicular than the distal $-COO^-$ group to the surface. In this way, the two
6
7
8 group more perpendicular than the distal $-COO^-$ group to the surface. In this way, the two
9
10 extremities of the molecule are forced to be at a different distance (*i.e.* height) from the surface.
11
12 Therefore, we propose that the two lobes at different z position revealed by STM profiles
13
14 correspond to the two ends of a single ASP molecule, with the highest lobe being the end with
15
16 the distal α -carboxylate $^-OOC-NH_2$. An analogous situation has been observed for methionine
17
18 on Au(111)⁴¹ where a single methionine molecule appeared as two bright spots, due to the fact
19
20 that, as evidenced by DFT calculations, the sulfur moiety and the carboxylic acid groups had
21
22 different orientations, pointing towards and away from the surface, respectively. Besides, the
23
24 distance between the two lobes in ASP is comparable to the distance between the two bright dots
25
26 in methionine, while is half the distance observed, for example, between the two bright spots
27
28 characterizing lysine pattern on Cu(110).⁴⁰ However, differently from methionine, lysine tends to
29
30 self-organize in dimers. So the bigger distance between its two double features confirms the
31
32 hypothesis of ASP single-molecule assembly.
33
34
35
36
37
38

39 A further statistical analysis revealed the distances between ASP molecules along the main
40
41 symmetry directions of the 2D pattern (line profiles 2 and 3 of Figure 4b, shown in Figure 4c),
42
43 which are, on average, (10.7 ± 0.5) Å and (13.0 ± 0.5) Å.

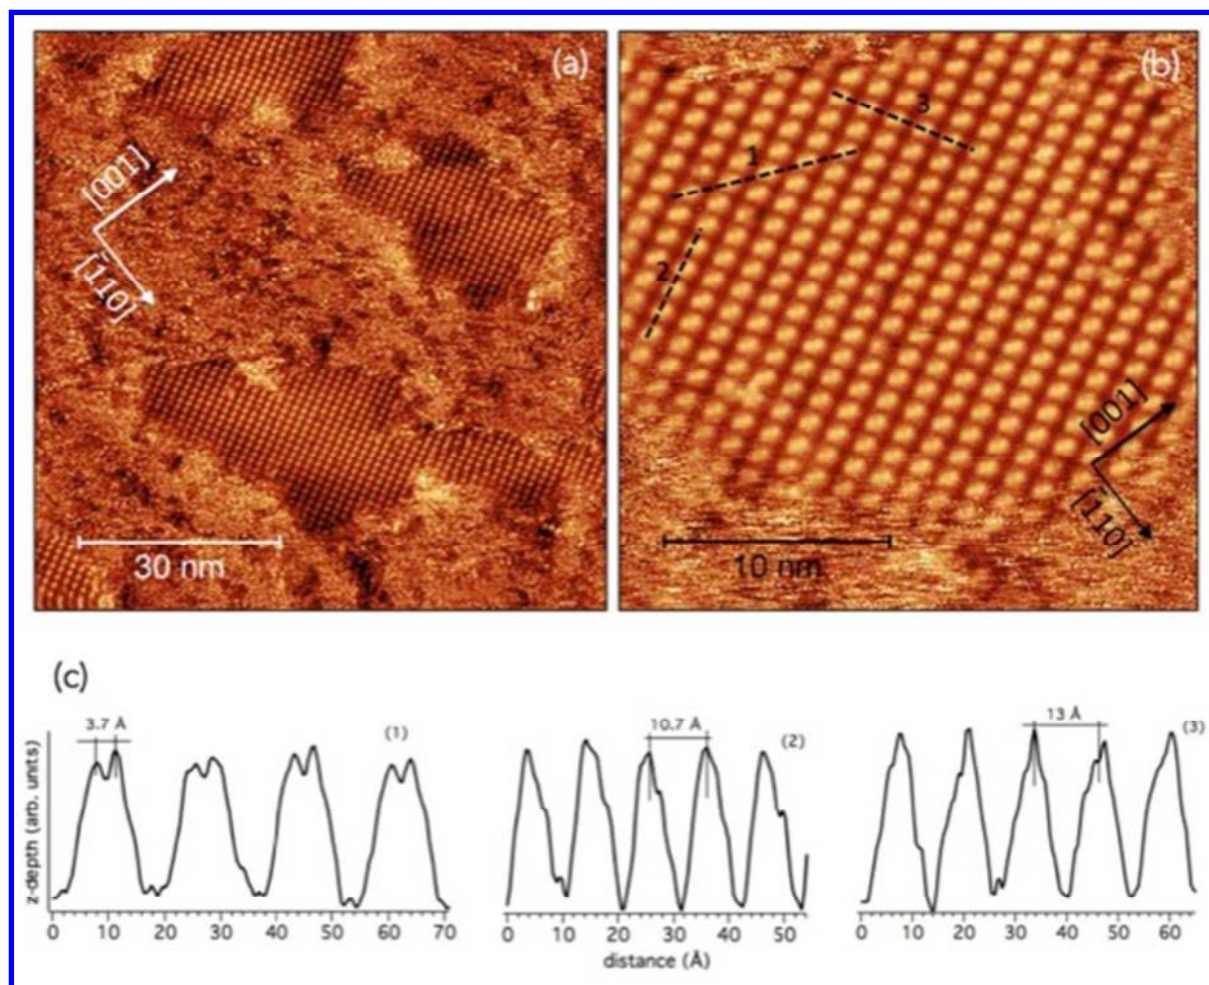

Figure 4. (a) Islands of ASP molecules, characteristics of the submonolayer regime. (b) Bilobate elements inside ASP islands. (c) Profiles extracted from dashed lines in (b). Image conditions are: (a) 84 nm x 85 nm, $V = 1.1$ V, $I = 100$ pA, (b) 25.2 nm x 25.5 nm, $V = 1.1$ V, 120 pA.

Comparing these experimental measurements and the distance between the two lobes with the crystallographic data, respectively, 1.11 nm, 1.33 nm and 0.44 nm, we are able to show a schematic representation of ASP molecules adsorbed on the Cu(110) rows and of the unit cell (Figure 5a), with the unit vectors represented by the $(-1, 3; -5, 1)$ matrix. ASP molecules are adsorbed diagonally across the closed-packed rows (Figure 5b) in the bidentate configuration already discussed in the XPS/PM-RAIRS section.

1
2
3 The distance between 2 neighboring ASP molecules, bigger than the weakest hydrogen bond
4 (roughly 4 \AA^2), and their anionic (COO^-/NH_2) state on the surface, prevent the creation of any
5
6 intermolecular hydrogen-bonding network. A similar situation with methionine adsorbed on
7
8 Cu(110) led to a total absence of the 2D array.³¹ Therefore, given the lacking of intermolecular
9
10 directions, we propose that molecule-substrate interactions, rather than molecule-molecule
11
12 interactions, are the driving force of the supramolecular assembly. The strict geometry
13
14 adsorption via the four O atoms, indicating a not-negligible ASP-Cu interaction, seems to
15
16 corroborate this suggestion.
17
18
19
20
21

22 It has to be noted that ASP molecules are accommodated along nonsymmetry directions,
23
24 destroying the symmetry planes of the underlying substrate. In this way the surface is bestowed
25
26 not only of point chirality due to the intrinsic chirality of ASP molecules, but also of chirality at
27
28 the organizational level. Besides, since domains of different chirality are not present on the
29
30 surface, we can conclude that the supramolecular assembly originated by ASP is able to modify
31
32 an achiral surface such as Cu(110) into a truly chiral surface with a global chirality, as also
33
34 observed, for example, in the adsorption of Gly-Pro on Cu(110).^{36,39,43}

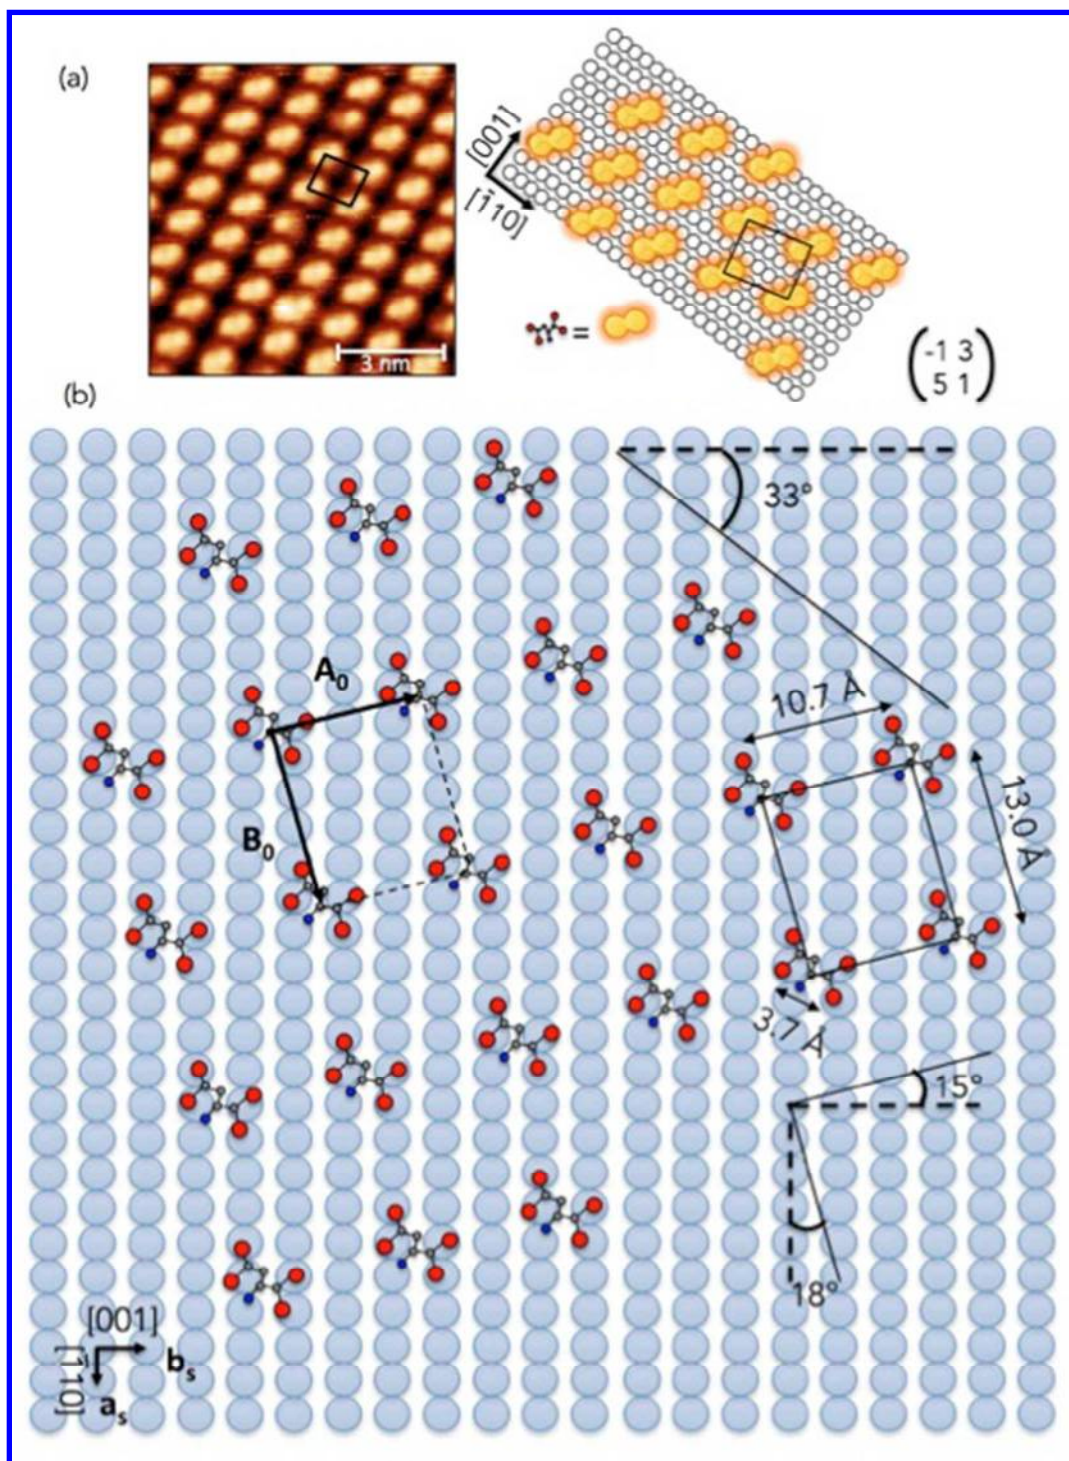

Figure 5. (a) ASP molecules 2D pattern from a high-resolution STM image (left, image conditions: 8.4 nm x 8.5 nm, 1.1 V, 120 pA) and depicted on copper rows in a schematic representation, together with the unit cell (right). (b) Adsorption model of ASP molecules, showing unit cell dimensions and the angles between the main symmetry directions of ASP pattern and Cu(110) crystallographic axis.

1
2
3 When the coverage increases (5 minutes dosing), ASP 2D pattern gradually covers the whole
4 surface (Figure 6a). In the high resolution image shown in Figure 6b, we can identify the lighter
5 areas as the beginning of the multilayer and fuzzy and not well-resolved areas (indicated by
6 dashed arrows), ascribable to Cu(110) surface. We do not have enough elements to examine
7 properly the multilayer pattern which, nonetheless, seems to be the characterized by more than
8 one structure, as indicated by solid arrows in Figure 6b. However, we can clearly see that, even if
9 the substrate is not still completely covered by the adsorbates, ASP molecules prefer
10 accommodating on other molecules rather than on the bare surface. Line profile of Figure 6c
11 traced along the solid line of Figure 6b shows the simultaneous presence of the substrate, the
12 monolayer and the starting overlayer. The multilayer way of growth can be explained
13 considering that, since molecules in the overlayer are not interacting with the surface, there is no
14 deprotonation of COOH/NH₃⁺ groups in the case of cationic gas phase molecules or of COOH
15 groups in the case of neutral gas phase molecules. Thus, differently from what seen in
16 submonolayer regime, they have the possibility of hydrogen bonding creation that can favor the
17 overlayer growth over the reaching of a saturated monolayer. Thus, this second stage of growth
18 is characterized by a prevalence of ASP-ASP interactions over ASP-Cu interactions.

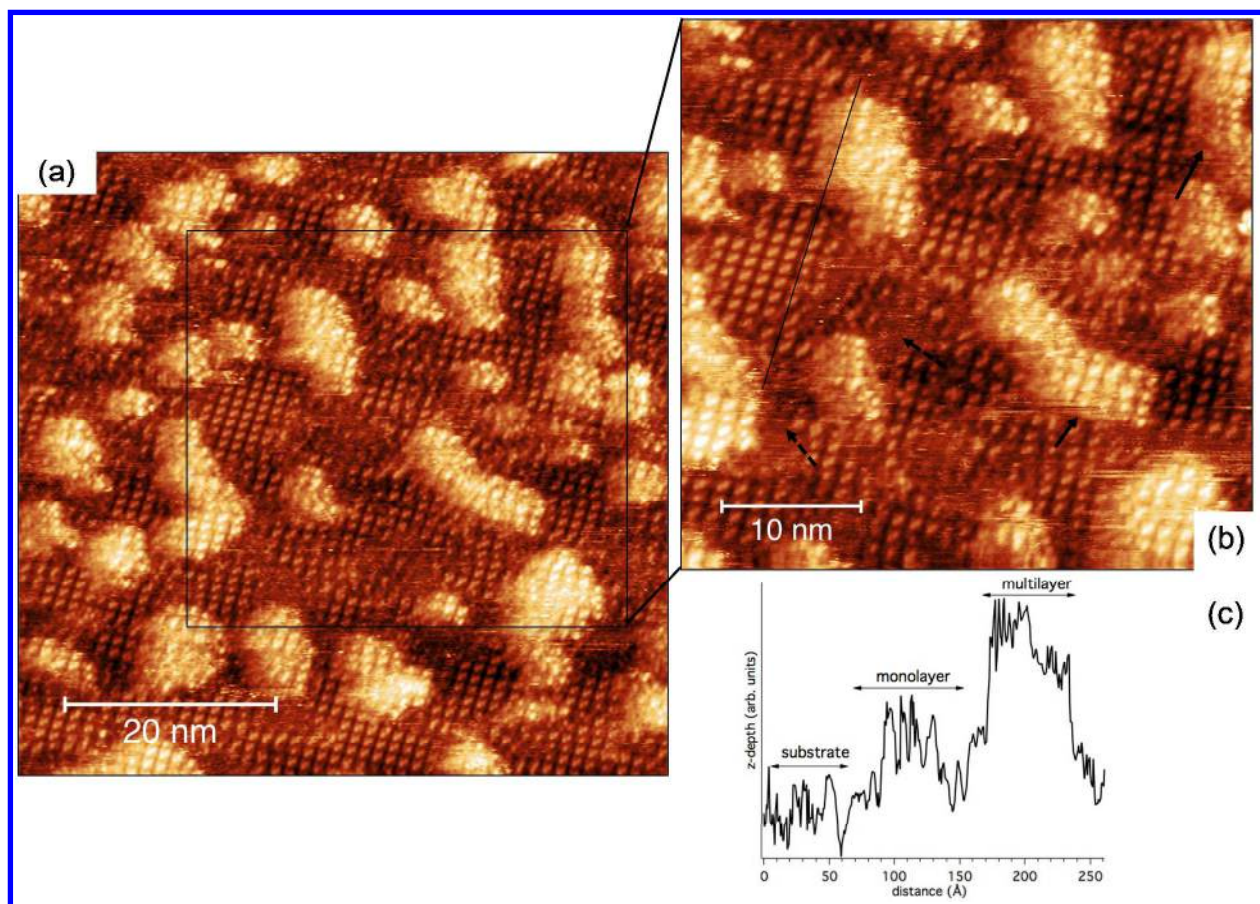

Figure 6. (a) Higher coverage (5 minutes dosing) of ASP: the ASP islands increase in number until reaching an almost complete covering of the underlying substrate. (b) High resolution STM image showing the co-existence of the multilayer (brighter areas) and of the Cu substrate, indicated by dashed arrows. Solid arrows indicate different co-existing multilayer structures. (c) Profile along the solid line traced in (b) to evidence the three elements present on the surface, substrate, monolayer and multilayer, and their different z position. Image conditions are: (a) 60.8 nm x 58.5 nm, 1.1 V, 50 pA; (b) 40.5 nm x 39 nm, 1.1 V, 50 pA.

CONCLUSIONS

We have realized the first surface science characterization of ASP films obtained by means of an ESI source. When aspartic acid is adsorbed on a Cu(110) surface, applying to the ESI a positive voltage, changes its state from cationic ($\text{COOH}/\text{NH}_3^+$) or neutral (COOH/NH_2) in the gas phase to anionic (NH_2/COO^-) on the surface. This implies that, respectively, either both the carboxylic acid groups and the protonated amine group or only the carboxylic acid group

1
2
3 undergo to a deprotonation process. As evidenced by our XPS and PM-RAIRS characterizations,
4 when the molecular coverage increases, molecules are adsorbed in their gas phase state. This
5 infers that the interaction with Cu is responsible for the hydrogen loss in the molecule. Besides,
6 the higher presence of hydrogen facilitates the growth of the multilayer, with the formation of a
7 $\text{NH}_3^+ \text{--COO-}$ hydrogen bonding network.
8
9

10
11
12
13
14
15 STM images, taken in the submonolayer regime (2 minutes dosing), show the creation of ASP
16 islands inside Cu terraces. Each island is made of ASP molecules arranged along a nonsymmetry
17 direction, diagonally crossing the close-packed rows and creating a chiral 2D network. In the 5
18 minutes dosing images, we can see both the substrate and the first structures of the overlayer
19 growing on the top of the underlying layer rather than on Cu. In the monolayer regime, the self-
20 assembly is guided by molecule-substrate interactions, while intermolecular interactions become
21 predominant for higher coverage, even before monolayer reached saturation.
