## ABSTRACT

**Background:** Hepatitis B surface antigen (HBsAg)-seroconversion, or loss of HBsAg and acquisition of anti-hepatitis B surface (HBs) antibodies, defines functional cure of chronic hepatitis B virus (HBV) infection. After HBsAg-loss, little is known regarding the development of anti-HBs antibodies and even less so in individuals co-infected with HIV.

**Objectives:** To determine anti-HBs antibody kinetics after HBsAg-loss and explore determinants of HBsAg-seroconversion in HIV-HBV co-infected patients.

**Study design:** Patients enrolled in the French HIV-HBV cohort were included if they had >1 study visit after HBsAg-loss. Individual patient kinetics of anti-HBs antibody levels were modeled over time using mixed-effect non-linear regression, whereby maximum specific growth rate and maximal level of antibody production were estimated from a Gompertz growth equation.

**Results:** Fourteen (4.6%) of 308 co-infected patients followed in the cohort exhibited HBsAg-loss, all of whom were undergoing antiretroviral therapy. Nine (64.3%) of these patients achieved HBsAg-seroconversion during a median 3.0 years (IQR=1.1-5.1) after HBsAg-loss. Across individuals with HBsAg-seroconversion, the fastest rates of antibody growth ranged between 0.57-1.93 year<sup>-1</sup> (population maximum growth rate=1.02) and antibody production plateaued between 2.09-3.66 log<sub>10</sub> mIU/mL at the end of follow-up (population maximal antibody levels=2.66). Patients with HBsAg-seroconversion had substantial decreases in HBV DNA viral loads ( $P=0.03$ ) and proportion with elevated ALT levels ( $P=0.02$ ) and HBeAg-positive serology ( $P=0.08$ ). No such differences were observed in those without HBsAg-seroconversion.

**Conclusions:** Most co-infected patients with HBsAg-seroconversion produced and maintained stable antibody levels, yet kinetics of anti-HBs production were much slower compared to those observed post-vaccination or after clearance of acute HBV-infection.

**KEYWORDS:** anti-HBs antibodies; HBsAg-seroconversion; antiretroviral therapy; kinetics; logistic growth model.

## **HIGHLIGHTS**

- Studies have yet to fully examine anti-HBs antibody development after HBsAg-loss.
- Nine HIV-HBV co-infected patients with HBsAg-loss and extensive viral suppression were prospectively followed.
- Rate of maximum antibody growth and level of maximum antibody development were much lower compared to post-vaccination or acute HBV.
- The modeling strategy presented herein could be useful for clinical trials evaluating novel agents and observational cohorts of HBV-infected patients.

## **BACKGROUND**

The most ideal therapeutic goal in patients chronically infected with hepatitis B virus (HBV) is loss of hepatitis B surface antigen (HBsAg) and appearance of anti-hepatitis B surface (HBs) antibodies, or HBsAg-seroconversion [1]. HBsAg-seroconversion is associated with decreased viral activity in the liver and regression of liver inflammation and fibrosis [2,3], hence why HBsAg-seroconversion is considered the hallmark of “functional cure” [4]. While almost all studies on the clinical advantages of HBsAg-seroconversion have been conducted in HBV mono-infected patients, similar trends have been noted in HIV-HBV co-infection [5].

Unfortunately, acquiring anti-HBs antibodies is an uncommon event for HIV-HBV co-infected individuals. HBsAg-loss itself occurs in roughly 1-2% of patients per year during treatment with potent nucleoside/nucleotide analogues [6,7]. In this group, an even smaller yet variable proportion converts to anti-HBs antibody-positive serology [5,6]. Co-infected patients are also known to exhibit fluctuating anti-HBs antibody profiles, which is noteworthy considering the improved survival linked to consistently detectable anti-HBs antibodies from the beginning of antiretroviral therapy (ART) [5].

Understanding of the development, persistence, and potential disappearance of anti-HBs antibodies could be further clarified by examining the kinetics of antibody levels after HBsAg-loss. Nevertheless, few studies to date have explored anti-HBs antibody levels *in vivo* during chronic hepatitis B infection, with none emphasizing the HIV-HBV co-infected population.

## **OBJECTIVES**

The aim of this study was to define the kinetics of anti-HBs antibodies, including the longitudinal determinants of HBsAg-seroconversion, in a small cohort of HIV-HBV co-infected patients exhibiting HBsAg-loss.

## **STUDY DESIGN**

### **Study participants**

Patients were selected from the French HIV-HBV Cohort Study as described previously [6]. Briefly, this prospective study recruited 308 patients from seven centers located in Paris and Lyon, France during May 2002-May 2003. Patients were included if they had HIV-positive serology confirmed by western blot and HBsAg-positive serology for at least six months. All data collection continued until 2010-2011.

For this study, subjects were selected if they achieved HBsAg-seroclearance and had at least two available anti-HBs antibody measurements thereafter. All patients provided written informed consent to participate in the cohort and the protocol was approved by the Hôpital Pitié-Salpêtrière and Hôpital Saint-Antoine Ethics Committees (Paris, France).

### **Assessing HBV-related parameters**

Plasma HBV DNA viral load was quantified using a commercial PCR-based assay [6]. Due to varying detection limits, undetectable HBV DNA was defined at <60 IU/mL.

Qualitative HBsAg and HBeAg were detected using a commercial enzyme-linked immunoassay at baseline and each yearly visit [6]. Anti-HBs antibodies were quantified during the same visits using one of the following commercially-available immunoassays: LIASON Anti-HBs Plus (measuring range=5-1000 mIU/mL; DiaSorin, Antony, France), Monolisa anti-HBs Plus (measuring range=0.01-1000 mIU/mL; Bio-Rad, Marnes-la-Coquette, France), or Architect anti-HBs (measuring range=0.01-1000 mIU/mL; Abbott Diagnostics, Rungis, France). High between-assay correlation and linearity over quantification ranges have been described for these assays [8,9].

Alanine aminotransferase (ALT) levels were quantified using standard methods. Liver fibrosis was assessed yearly by a non-invasive method: Fibrotest® and/or Fibroscan® (Echosens, Paris, France). Cutoffs for METAVIR F3 fibrosis were applied (Fibrotest®, F3=0.59 and Fibroscan®, F3=7.6 kPa) [10,11].

### **Statistical analysis**

*HBsAg-seroclearance* was defined as HBsAg-loss (no longer HBsAg-positive) during follow-up and *HBsAg-seroconversion* was defined as HBsAg-loss and acquiring anti-HBs antibody titers >10 mIU/mL. Statistical analysis was performed using STATA statistical software (v12.1, College Station, TX) and R 3.3.1 and a *P*-value of <0.05 was considered significant.

We initially described the evolution of biological and clinical parameters during overall follow-up in the cohort study to determine if there were any particular differences between patients with and without HBsAg-seroconversion. Patient characteristics were compared between inclusion visit and last follow-up visit. A paired-sample Wilcoxon signed-rank test was used for continuous variables and Pearson  $\chi^2$  test or Fisher's exact test for categorical variables.

In subsequent analysis, we defined baseline as the study visit prior to HBsAg-seroclearance and follow-up as every yearly visit until last available anti-HBs antibody level, end of follow-up, study discontinuation, or death; whichever occurred first. *In vivo* kinetics of anti-HBs antibody after HBsAg-seroclearance were examined. Previous kinetic models have been mostly drawn from studies on immune responses post-vaccination [12], lending to the assumption that anti-HBs antibody levels would have an immediate increase upon vaccination with an exponential decay shortly thereafter [13]. These models might not fully reflect anti-HBs antibody levels during clearance of HBV infection, where antigen-independent proliferation of memory B cells and plasma cells likely reach a state of homeostatic equilibrium and continuously produce antibodies at a specific threshold [14]. Consequently, we modeled anti-HBs antibody kinetics using a Gompertz growth equation [15], defined as follows:

$$y = A \cdot e^{-k_1 e^{-k_2 t}}$$

where  $A$  describes maximal antibody levels,  $k_1$  the delay in anti-HBs antibody response, and  $k_2$  the maximum growth rate per year. Anti-HBs antibody levels <10 mIU/mL and >1000 mIU/mL were left- and right-censored, respectively. Population and individual parameters were estimated with nonlinear mixed-effect models taking into account inter-individual variability (IIV) (Supplementary Materials).

## RESULTS

### Description of the study population

Of the 308 patients in the cohort study, 17 with documented HBsAg-seroclearance were considered. Three of these patients had only one anti-HBs antibody measurement after HBsAg-seroclearance and were excluded. In total, 14 patients were included in analysis.

Patients were predominately male (93%), coming from an intermediate or high zone of HBV-prevalence (43%), with a median age of 42 years (IQR=38-52). From the start of the cohort study, median duration of known HIV-infection was 6 years (IQR=4-13) and median CD4+ cell count at 440/mm<sup>3</sup> (IQR=303-554), while three patients (21.4%) had presented with an AIDS-defining illness. One and two patients also had positive serology for hepatitis C and D virus, respectively.

### **Rates and determinants of HBsAg-seroconversion**

HBsAg-seroclearance occurred after a median 4.6 years (IQR=2.1-7.4) of follow-up in the cohort. Nine (64.3%) patients achieved HBsAg-seroconversion during a median 3.0 years (IQR=1.1-5.1) after HBsAg-seroclearance. HBsAg-seroconversion was identified either at the same visit as HBsAg-seroclearance ( $n=5$ ) or 0.9-2.3 years after the first HBsAg-negative result ( $n=4$ ). Two patients fluctuated back to anti-HBs antibody-negative serology once during follow-up while ending with anti-HBs antibody-positive serology, one of whom had an HBsAg/anti-HBs antibody-positive profile before achieving HBsAg-seroclearance.

Table 1 summarizes the clinical differences between cohort inclusion and last follow-up visits, while stratified between those with versus without HBsAg-seroconversion. At cohort inclusion, patients with HBsAg-seroconversion were more likely to have HBeAg-positive serology, higher ALT levels and HBV-DNA viral loads; yet none of these differences was significant. During follow-up, significant changes in HBV-DNA viral loads ( $P=0.03$ ) and proportion with elevated

ALT levels ( $>35$  IU/L,  $P=0.02$ ) were observed in patients with HBsAg-seroconversion. In contrast, there were no significant changes in HIV- or HBV-related parameters from cohort inclusion to last follow-up visit in those without HBsAg-seroconversion. ART was administered in all 14 patients during follow-up, with no noticeable difference between seroconversion groups (Supplementary Material).

Liver fibrosis levels were stable for most patients during follow-up (Supplementary Material). No cases of portal hypertension, decompensated liver, end-stage liver disease, hepatocellular carcinoma, or liver-related death occurred in any of the included patients.

### **Kinetics of anti-HBs antibodies after HBsAg-loss**

In total, 54 samples were available for 9 patients after HBsAg-loss. We selected a model without IIV for  $k_1$ . The estimate for  $k_1$  was 2.49 (RSE=26%) and maximum growth rate,  $k_2$ , was 1.02 years<sup>-1</sup> (RSE=30%) showing 47% of IIV. Population maximum anti-HBs antibody titer was 2.71 log<sub>10</sub> mIU/mL (relative standard error, RSE=10%) showing 20% of IIV. The additive error term, measuring the difference between predicted and observed values, was 0.35 (RSE=1%) log<sub>10</sub> mIU/mL.

Model parameters of anti-HBs antibody kinetics after HBsAg-seroclearance are given for each patient in Table 2, noting that one patient had an insufficient number of time-points to obtain estimates. Model fit was good (Figure 1). Individual maximum growth rate somewhat varied between patients (0.57-1.93 year<sup>-1</sup>). Strong yet non-significant correlations were observed between  $k_2$  and nadir CD4+ (Spearman's rho=-0.48,  $p=0.2$ ) and concomitant CD4+ cell count (rho=-0.53,  $p=0.18$ ) at the moment of HBsAg-seroconversion. Five patients had a maximum level of log<sub>10</sub> antibody units estimated between 2.09-2.66 log<sub>10</sub> mIU/mL and two patients  $>3.0$

$\log_{10}$  mIU/mL. There were no significant correlations between maximum levels of antibody units and ALT (Spearman's  $\rho=0.15$ ,  $p=0.7$ ), CD4+ cell count ( $\rho=-0.07$ ,  $p=0.9$ ), and nadir CD4+ cell count ( $\rho=-0.32$ ,  $p=0.4$ ) at HBsAg-seroconversion.

In order to understand the projected development of anti-HBs antibodies over eight years, we simulated anti-HBs antibody trajectories of 1000 subjects by drawing individual parameters from the population parameter distribution among those with HBsAg-seroconversion. As shown in Figure 2, we predicted that 300 (30.0%) simulated patients would eventually reach the upper limit of quantification ( $>1000$  mIU/mL) after a median 3.3 years (IQR=2.4-4.3). At the end of eight years, 657 (65.7%) simulated patients would reach  $>100$ - $1000$  mIU/mL, while the remaining 43 (4.3%) would have levels persisting between  $>10$ - $100$  mIU/mL.

## DISCUSSION

In this small group of patients exhibiting HBsAg-loss, 64% progressed further to HBsAg-seroconversion during a median three years of follow-up. This proportion was slightly higher compared to other cohorts of treated co-infected patients (14-50%) [5,7,16,17] and somewhat similar to HBV mono-infected patients (50-71%) [18–21]. Nevertheless, comparisons to other cohorts are oftentimes difficult, as most have insufficient follow-up and the low rates of HBsAg-seroclearance in general give rise to equally small sample sizes.

Anti-HBs antibody production is important for several reasons. First, anti-HBs antibodies, especially those targeted to the preS1 domain, have the capacity to neutralize circulating virus [22]. Modeling data from *in vitro* experiments have also shown that anti-HBs antibodies can block the release of HBV and HBsAg sub-particles from infected hepatocytes [23]. These

antiviral mechanisms could be beneficial even during viral suppression under anti-HBV agents, such as TDF, when virus is known to circulate at low levels below detection thresholds of most conventional PCR assays [24]. Second, levels of hepatitis B core antigen-specific CD8+ T cells, associated with cell-mediated clearance of HBV infection, are almost completely undetectable decades after HBsAg-seroconversion [25]. It would then be assumed that humoral responses linked to antibody production would play a dominant role in preventing HBV reactivation. Finally, HBsAg is expressed on the membrane of infected hepatocytes [26], to which recognition by anti-HBs antibodies could lead to cytotoxicity and clearance of infected liver cells [27]. There is, therefore, an inherent interest in studying how anti-HBs antibody production is achieved after HBsAg-loss.

After applying a sigmoidal model of antibody growth, we were able to characterize several remarkable features of anti-HBs antibody production during HBsAg-seroconversion. When examining the maximum rate of antibody production, there was slight variability between patients, ranging from 0.57-1.93 year<sup>-1</sup>. In studies using dynamic modeling, the highest rates of antibody production have been observed after vaccination among immunocompetent populations, with estimates around 0.94 per day [28]. These rates are much lower during clearance of acute infection at 0.96-1.32 per month, while the lower bounds of these estimates are strongly associated with low virus production [14]. We observed a much lower rate of antibody production compared to these previous studies. Whether this attenuated rate is due to the pathophysiological features of chronic infection, immunocompromised status, or a combination of both are difficult to determine given that no data of this kind are available in HBV mono-infected patients.

The model asymptotes obtained in our study showed that only two patients had anti-HBs antibody levels plateauing consistently above 1000 mIU/mL, whereas the remainder had levels

hovering around 123-457 mIU/mL. How this translates to clinical outcomes is difficult to state given the lack of evidence correlating long-term anti-HBs antibody levels and liver-related morbidity and mortality. Interestingly, these levels are similar to vaccine response or HBsAg-seroconversion in immunocompromised individuals, particularly HIV-positive [29] or liver transplant patients [30,31], and much lower for vaccine response in healthy individuals [32].

Notwithstanding the potential for inadequate power, certain determinants were noted between patients with HBsAg-seroclearance who did versus did not develop anti-HBs antibodies. Patients with HBsAg-seroconversion appeared to have gone from a more active form of infection, with higher levels of replication, higher proportion with HBeAg-positive serology and higher ALT levels before evolving towards inactive infection. The accelerated development of anti-HBs antibodies has been observed in other studies among HIV-HBV co-infected patients, yet this was strongly linked to severe immunocompromised status and immunoreconstitution after ART-initiation [17,33] and thus could represent a type of “immunoreactive” phase of HBV-infection. Indeed, patients with HBsAg-seroconversion did have lower levels of nadir and current CD4+ cell counts prior to HBsAg-loss and maximum antibody growth rate was inversely correlated with nadir CD4 cell count; however, none of these associations were significant. Determining if improvements in common immunological deficiencies related to antibody acquisition, such as B cell proliferation upon activation [34] and HBsAg-specific T helper 1 cells [35,36], could help establish the components of immunity responsible for these observations in co-infected individuals.

Other genetic determinants could have also explained our results. For instance, specific human leukocyte antigen class II alleles, notably DRB1 and DQB1, have been associated with antibody response to HBV vaccine [37]. The relationship between these alleles and HBsAg-

seroconversion has yet to be studied during the natural history of chronic HBV-infection and as human genetic data were not collected in our study, we cannot infer on its particular role.

Despite the advantages of HBsAg-seroconversion obtained from *in vitro* findings, the clinical benefit of acquiring anti-HBs antibodies is debatable. In HIV-infected patients with previous exposure to HBV-infection, rates in all-cause mortality were not significantly different between those who did versus did not acquire anti-HBs antibodies [5]. Likewise, we saw no particular improvement in liver fibrosis markers for any of the patients in this cohort, regardless of anti-HBs antibody acquisition. One explanation could be that stable liver fibrosis levels are generally problematic for the HIV-HBV co-infected population, even during antiretroviral therapy containing more potent anti-HBV treatments [38]. Alternatively, as this was a population of HBsAg-negative patients with low prevalence of cirrhosis, especially when considering the FibroScan® alone, no further declines in fibrosis would be anticipated during such a short follow-up period.

There are certain limitations that need to be addressed. First, samples were taken at yearly intervals for almost all patients and hence the exact timing of HBsAg-seroconversion would be challenging. Infrequent sampling also made it difficult to test for oscillations in anti-HBs antibody levels during follow-up. Second, anti-HBs antibody levels were quantified from a variety of assays across centers, with some demonstrating moderate intra-assay variability [39]. Between-patient comparability could have been affected; nevertheless, the uniformity of assays within centers, with the exception of modifications in reagents with the Biorad assay [9], would limit measurement bias in the kinetic parameters obtained from individual patients.

In conclusion, of the two-thirds of patients with HBsAg-seroclearance who continued further to HBsAg-seroconversion, most were able to produce and maintain stable levels of antibodies but some did exhibit vast fluctuations in antibody production. The finding that non-invasive markers

of fibrosis did not subside after HBsAg-seroconversion raises questions on whether this end-point is an adequate representation of decreased risk in liver-disease for HIV-HBV co-infected patients, yet this would need further validation in studies with higher prevalence of pre-treatment cirrhotics and/or longer follow-up. Future research should aim to develop if any benefit in anti-HBs antibody production could extend towards switching to a non-anti-HBV containing antiretroviral regimen.

## **CONFLICT OF INTEREST**

The authors declare no conflicts of interest relevant to the manuscript.

## **ETHICAL APPROVAL**

All patients provided written informed consent to participate in the cohort and the protocol was approved by the Hôpital Pitié-Salpêtrière and Hôpital Saint-Antoine Ethics Committees (Paris, France) in accordance with the Helsinki Declaration.

## **ACKNOWLEDGEMENTS**

The authors are grateful to all patients and clinical teams for their commitment to the French HIV-HBV Cohort Study. We acknowledge H. Rougier, M. Sébire-Le Cam, and L. Roguet for managing the logistics of the French HIV-HBV Cohort; G. Pannetier and F. Carrat for their help

in data management; and Pr J.-F. Flejou and E. Roux of the Tumorotheque HUEP at Saint-Antoine Hospital for storing samples.

Funding: This work was supported in part by the Institut de Médecine et d'Epidémiologie Appliquée and received additional grants from ANRS (Agence Nationale de Recherche sur le Sida et les Hépatites). Gilead Sciences, Inc. provided an unrestricted grant for the French HIV-HBV cohort and was not involved in any part of the data collection, analysis, and manuscript writing. Post-doctoral fellowships from the ANRS and SIDACTION were awarded to AB. LC was funded by the UK Biotechnology and Biological Sciences Research Council (grant reference 1698:BB/L001330/1).

## FIGURE LEGENDS

### **Figure 1. Kinetics of anti-HBs antibodies for individual HIV-HBV co-infected patients after hepatitis B surface antigen (HBsAg) seroclearance.**

Time starts at the visit prior to HBsAg-seroclearance and continues until end of follow-up. Levels of anti-HBs antibodies are plotted at each time point, with separate panels depicting a different patient. Fitted lines from the Gompertz model, as described in the methods, are also given. The dashed grey lines represent the lower and upper limit of quantification, dots observations between these limits of quantification, triangles observations below the lower limit of quantification and squares observations above the upper limit of quantification. One patient with HBsAg-seroconversion is not included as they did not have enough time-points needed to estimate model parameters.

### **Figure 2. Simulated kinetics of anti-HBs antibodies using individual parameters**

Each line represents a simulated patient's trajectory of anti-hepatitis B surface (HBs) antibody growth over eight years of follow-up. A total of 1000 subjects were simulated by drawing individual parameters from the population parameter distribution (of a Gompertz model) among those with HBsAg-seroconversion.

## TABLES

**Table 1. Evolution of clinical characteristics during follow-up in HIV-HBV co-infected patients without and with HBsAg-seroconversion**

	Not acquired anti-HBs antibodies (n=5)			Acquired anti-HBs antibodies (n=9)		
	Cohort inclusion	Last follow-up visit	P*	Cohort inclusion	Last follow-up visit	P*
CD4+ cell count, /mm <sup>3</sup> ‡	582 (486-802)	603 (392-694)	0.9	316 (278-405)	431 (266-527)	0.9
Detectable HIV-RNA	2 (40.0)	1 (20.0)	0.9	3 (33.3)	1 (11.1)	0.6
HIV-RNA, log <sub>10</sub> copies/mL‡	<1.70 (<1.70-1.96)	<1.70 (<1.70-<1.70)	0.9	<1.70 (<1.70-2.87)	<1.70 (<1.70-<1.70)	0.9
Known duration of HBV-infection, years‡	9.1 (6.3-11.1)	--	<i>ntp</i>	6.0 (1.1-12.6)	--	<i>ntp</i>
Detectable HBV-DNA	2 (40.0)	1 (20.0)	0.9	4 (44.4)	0	0.08
HBV-DNA, log <sub>10</sub> IU/mL‡	1.82 (<1.78-2.28)	<1.78 (<1.78-<1.78)	0.9	2.28 (<1.78-4.63)	<1.78 (<1.78-<1.78)	0.03
HBeAg-positive serology	0	0	<i>ntp</i>	4 (44.4)	0	0.08
Concomitant LAM	4 (80.0)	3 (60.0)	0.9	7 (77.8)	6 (66.7)	0.9
Concomitant TDF	0	3 (60.0)	0.17	2 (22.2)	5 (55.6)	0.3
ALT, IU/L‡	39 (29-55)	35 (33-43)	0.9	50 (45-56)	31 (20-34)	0.07
ALT > 2X ULN	0	0	<i>ntp</i>	1 (12.5)	0	0.5
ALT > ULN	3 (60.0)	2 (40.0)	0.9	7 (87.5)	2 (22.2)	0.02

Numbers (%) are given for most variables above, while medians (IQR) are provided for those designated with (‡). ALT levels at 35

IU/L were defined as the upper limit of normal (ULN).

\*Significance between groups determined using paired-sample Wilcoxon signed-rank test for continuous variables and Pearson  $\chi^2$

test or Fisher's exact test for categorical variables. *ntp* – no test performed

**Table 2. Detailed description of patients with HBsAg-seroconversion and parameters of anti-HBs antibody kinetics**

Patient number	Prior treatment*	Sex	Nadir CD4 /mm <sup>3</sup>	CD4 /mm <sup>3</sup> †	CDC stage	HIV-RNA (copies/mL) †	ALT (IU/L) †	A [log <sub>10</sub> mIU/mL]	k <sub>2</sub> (yr <sup>-1</sup> )	t <sub>max</sub> (yr)
111	LAM→TDF→LAM/TDF	M	324	690	A	<50	72	‡	‡	0.9
131	LAM→TDF	M	321	522	C	<50	32	2.66	0.96	3.0
140	LAM→ADV	M	107	262	A	<50	55	3.40	0.70	5.1
416	∅	F	179	417	A	<50	25	3.66	1.59	4.7
516	LAM/TDF	M	281	623	A	<50	17	2.58	0.57	6.6
526	<u>IFN</u> →LAM	M	205	498	B	<50	42	2.66	0.87	5.8
527	<u>LAM/Peg-IFN (3X)</u> →LAM/TDF	M	194	377	A	<50	33	2.09	1.39	6.7
1212	<u>LAM</u> →LAM/TDF	M	82	232	C	<50	18	2.66	1.93	3.0
1302	LAM→LAM/TDF	M	129	220	B	<50	52	2.59	1.07	3.0

Model parameters  $A$  and  $k_2$  are respectively the asymptote (or maximum antibody levels) and maximum growth rate.  $T_{\max}$  is the total follow-up duration after HBsAg-seroclearance.

\*Only anti-HBV treatment leading up to HBsAg-seroconversion: ∅, no treatment; ADV, adefovir; IFN, standard interferon-α; LAM, lamivudine; Peg-IFN, pegylated-interferon (only patient with Peg-IFN was treated three times in combination with LAM during a period of ten years); TDF, tenofovir. Underlined treatments were administered exclusively prior to cohort inclusion.

†At first visit where anti-HBs antibodies appeared.

‡Parameters were unable to be estimated due to lack of follow-up time points.
