*Langmuir*, **Just Accepted Manuscript** • DOI: 10.1021/acs.langmuir.7b03980 • Publication Date (Web): 11 Dec 2017Downloaded from <http://pubs.acs.org> on December 12, 2017**Just Accepted**

“Just Accepted” manuscripts have been peer-reviewed and accepted for publication. They are posted online prior to technical editing, formatting for publication and author proofing. The American Chemical Society provides “Just Accepted” as a free service to the research community to expedite the dissemination of scientific material as soon as possible after acceptance. “Just Accepted” manuscripts appear in full in PDF format accompanied by an HTML abstract. “Just Accepted” manuscripts have been fully peer reviewed, but should not be considered the official version of record. They are accessible to all readers and citable by the Digital Object Identifier (DOI®). “Just Accepted” is an optional service offered to authors. Therefore, the “Just Accepted” Web site may not include all articles that will be published in the journal. After a manuscript is technically edited and formatted, it will be removed from the “Just Accepted” Web site and published as an ASAP article. Note that technical editing may introduce minor changes to the manuscript text and/or graphics which could affect content, and all legal disclaimers and ethical guidelines that apply to the journal pertain. ACS cannot be held responsible for errors or consequences arising from the use of information contained in these “Just Accepted” manuscripts.

# Extracellular vs. Intracellular Degradation of Nanostructured Silica Particles

Yupeng Shi, Christophe H elary, Bernard Haye and Thibaud Coradin\*

**ABSTRACT:** Silica nanoparticles appear as promising drug carriers for intracellular delivery. However the mechanisms by which they are degraded within cells remain largely unknown. In this context, we have prepared three types of PEGylated fluorescent silica nanoparticles with various internal structures (core-shell bio-composite, multilayered and hollow mesoporous) and studied their degradation in buffer, in culture medium and in contact with human dermal fibroblasts. All particles were prone to dissolve in solution, leading to an increase of porosity and/or precipitation of new colloids and eventually fragmentation, with a faster rate in medium compared to buffer. All particles were also uptaken by cells without significant cytotoxic effect. Their intracellular degradation occurred faster than in suspension but following almost similar dissolution mechanisms. These results strongly suggest that, in these conditions, silica nanoparticles must be primarily considered as hydrolytically degraded and not biodegraded, a point of importance for their future application in drug delivery.

## INTRODUCTION

The unique features of nanomaterials have led to their rapid development in the biomedical field, for example in the delivery of drugs and genes, or for bio-imaging and diagnosis.<sup>1-4</sup> In this context, understanding the interactions between nanoparticles and cells is crucial to elucidate the true nature of the nanoparticle-mediated biological effects. In particular, although efforts have been devoted to discover the factors that affect the cellular uptake, toxicity and degradation of nanomaterials,<sup>5-8</sup> a detailed understanding of their intracellular fate remains a true challenge.

Silica nanomaterials have been used on an industrial scale for a long time in various technological fields.<sup>9</sup> They also have a variety of unique properties, such as versatile synthesis, controllable size and architecture, easy surface modification, and relatively stable and homogeneous chemical composition, which endow them with many advantages for biomedical applications.<sup>10</sup> A number of silica-based nanomaterials with engineered shape, structure and surface modification, such as solid nanoparticles/rod, mesoporous, hollow, multilayered, core-shell nanostructure as well as bio-composite nanomaterials, have been synthesized and evaluated as drug/gene delivery systems.<sup>11-16</sup> However, in order to use them for intracellular delivery, successive steps of internalization, cellular trafficking, drug release and externalization should be finely controlled.<sup>17-19</sup> Among these, the control of intracellular behavior of the nanoparticles remains highly challenging, especially because the question whether mammalian cells

1  
2  
3  
4 exhibit specific biological mechanisms to degrade silica remains open.<sup>20,21</sup> Indeed, the  
5  
6 degradation of silica nanoparticles in biologically-relevant conditions has been studied in  
7  
8 details and recently reviewed by Croissant *et al.*<sup>21</sup> The accumulated evidences point out  
9  
10 the dynamic equilibrium between silica dissolution and re-deposition, which is influenced  
11  
12 by factors such as pH, temperature, silica concentration and porosity.<sup>22-25</sup> Dove *et al.*  
13  
14 demonstrated that the primary dissolution event consists in the detachment of a [SiO<sub>4</sub>]  
15  
16 tetrahedron from the silica surface,<sup>26</sup> that is expected to be influenced by (i) the  
17  
18 coordination number of Si atoms at the surface, (ii) the stability and reactivity of the  
19  
20 detached species and (iii) the extent of the surface and its accessibility to water.<sup>27</sup> As  
21  
22 reviewed by Ehrlich *et al.*,<sup>28</sup> the first two parameters are related to the condensation  
23  
24 degree of the silica network and the relative abundance of protonated, neutral and  
25  
26 deprotonated silanols while the last parameter is controlled by the specific surface area of  
27  
28 the system and the presence of adsorbed molecules. For instance, it has been  
29  
30 demonstrated that the degradation rate of silica gels with similar specific surface area  
31  
32 could be tuned by their condensation degree,<sup>29</sup> and that the presence of a protein coating  
33  
34 could slow down the dissolution process.<sup>30</sup> In parallel, Kuroda *et al.* showed that  
35  
36 mesoporous particles dissolve faster than plain silica particles of the same sizes.<sup>31</sup> The  
37  
38 enhanced dissolution rate of silica particles with increasing pH and/or in the presence of  
39  
40 phosphate ions has also been reported at several occasions.<sup>21,27,28,32</sup> Concerning the  
41  
42 possible redeposition of the dissolved species, a comparative study of two types of  
43  
44 mesoporous silica nanoparticles showed that the degradation of MCM-41-type  
45  
46  
47  
48  
49  
50  
51  
52  
53  
54  
55  
56  
57  
58  
59  
60

1  
2  
3  
4 mesoporous silica occurred from the outer surface, while for SBA-15 nanoparticles a  
5  
6 decrease in microporosity and an increase in mesoporosity suggested a complex inner  
7  
8 solubilization/recondensation process.<sup>33</sup> Other studies have suggested that the  
9  
10 degradation of mesoporous nanoparticles may simultaneously proceed from the outer and  
11  
12 the inner surfaces.<sup>34,35</sup>  
13  
14  
15  
16  
17

18 Much less is known about the intracellular fate of silica nanoparticles. Earlier reports  
19  
20 on the evolution of bionanocomposite silica-biopolymer nanoparticles within the  
21  
22 intracellular space of mammalian cells have suggested that, after 24 h, only the  
23  
24 bio-organic fraction was degraded while the inorganic part remained intact.<sup>36,37</sup> Further  
25  
26 experiments performed with mesoporous nanoparticles evidenced that their cellular  
27  
28 uptake was followed by their exocytosis. In addition the released particles were  
29  
30 associated with proteins located in the cellular membrane or involved in the vesicular  
31  
32 trafficking.<sup>38</sup> However no modification in particle size or morphology was reported. A  
33  
34 first insight in the intracellular dissolution pathway of plain silica nanoparticles was  
35  
36 obtained by Quignard *et al.* through a combination of TEM imaging and identification of  
37  
38 the products of their degradation.<sup>39</sup> A decrease of particle size was observed and  
39  
40 attributed to surface erosion as a result of the dissolution equilibrium of silica. Since then,  
41  
42 further evidences of the ability of silica to dissolve intracellularly were accumulated.<sup>40-43</sup>  
43  
44  
45  
46  
47  
48  
49 Yet, considering the complexity of the accompanying trafficking events, that can include

1  
2  
3  
4 At present, there are mainly three strategies to load small molecular drugs and  
5  
6 biological macromolecules within silica nanomaterials. The first is to mix the drugs with  
7  
8 the silica precursor to form nanocomposites.<sup>44,45</sup> The second is through the layer-by-layer  
9  
10 method.<sup>46,47</sup> The third involves the impregnation of mesoporous or hollow silica  
11  
12 nanoparticles.<sup>48,49</sup> As far as we know, there is no report comparing the degradation  
13  
14 behavior of these three types of silica nanoparticles in biologically-relevant conditions.  
15  
16  
17 With this purpose, we have prepared PEGylated fluorescent silica particles with different  
18  
19 internal structures (bio-composite, multilayered and hollow mesoporous) and studied  
20  
21 their time evolution in abiotic (phosphate buffer, culture medium) conditions and then in  
22  
23 the presence of normal human dermal fibroblasts. Structural degradation and dissolution  
24  
25 kinetics of the nanoparticles were studied in parallel with their cytotoxicity. The  
26  
27 here-gathered data suggest that, for these systems, the intracellular fate of silica  
28  
29 nanoparticles can be explained on the sole basis of physico-chemical processes. This  
30  
31 provides new and strong evidences that, in the intracellular space, silica nanoparticles  
32  
33 should be considered as hydrolytically-degradable rather than biodegradable materials, a  
34  
35 result of great consequences for the design of silica-based biomaterials.

25 **Synthesis of PEGylated BSA@SiO<sub>2</sub> Nanoparticles (BSNPs).** BSA@SiO<sub>2</sub>  
26  
27 nanoparticles were synthesized via a modified Stöber method.<sup>50</sup> First, 30 mg BSA were  
28  
29 diluted in 3 mL deionized (DI) water and then added to 20 mL of ethanol containing 2  
30  
31 mL ammonia. After 5 minutes, 1 mL TEOS was added under stirring for 1 hour. Lastly,  
32  
33 50 μL APTES-FITC was added three times every two hours, followed by vigorous  
34  
35 stirring for 24 hours. Another 50 μL APTES was added and after for 24 hours under  
36  
37 stirring, amine-functionalized BSA@SiO<sub>2</sub>-NH<sub>2</sub> particles were obtained, recovered by  
38  
39 centrifugation and washed with ethanol twice. Next, BSA@SiO<sub>2</sub>-NH<sub>2</sub> were re-dispersed  
40  
41 in 5 mL of PBS (phosphate buffer saline, 1X), and 8 mg of NHS-PEG<sub>5000</sub>-MAL was  
42  
43 added.<sup>51</sup> The mixture was then stirred at room temperature for 2 hours before harvesting  
44  
45 PEGylated particles by centrifugation.

### **Synthesis of PEGylated Hollow Mesoporous Silica Nanoparticles (HSNPs).**

Fluorescent uniform ~100 nm sized SiO<sub>2</sub> nanoparticles were obtained using a modified Stöber method.<sup>52</sup> In a typical synthesis, 35.7 mL of absolute ethanol was mixed with 5 mL water and 0.8 mL of ammonia and stirred for 5~10 minutes at room temperature. Then 1 mL of TEOS and 1 mL of APTES-FITC were added and the mixture was allowed to react at room temperature for 1 h. Afterward, SiO<sub>2</sub> nanoparticles were washed with water and ethanol and suspended in 20 mL of water. To prepare hollow mesoporous silica nanoparticles,<sup>53</sup> CTAB (2 g) and TEA (20 mg) were dissolved in 20 mL of DI water and stirred at room temperature for 1 h. Then, 10 mL of the previous SiO<sub>2</sub> suspension was added and stirred at room temperature for 1 h before addition of 0.15 mL of TEOS. The mixture was stirred for 1 h at 80°C in a water bath and the mixture was then cooled down to 50°C followed by addition of 636 mg of sodium carbonate (Na<sub>2</sub>CO<sub>3</sub>), under constant stirring for 30 min. To remove the CTAB, the product was extracted for 24 h with a 1 wt% solution of NaCl in methanol at room temperature. This process was carried out for at least 3 times to ensure complete removal of CTAB. For PEG grafting, 8 mg of the recovered particles were dispersed in 50 mL of DMSO and then 500 µL of APTES were added. After the mixture was stirred for 20 hours, amine-functionalized HSNPs (HSNP-NH<sub>2</sub>) were recovered by centrifugation and washed with ethanol twice. Next, HSNP-NH<sub>2</sub> particles were re-dispersed in 5 mL of DMSO, and 8 mg of NHS-PEG<sub>5000</sub>-MAL was added. The mixture was then stirred at room temperature for 2 hours under anhydrous conditions before being harvested by centrifugation.

1  
2  
3  
4       **Synthesis of PEGylated Double-layered PEI-Silica Nanoparticles (PSNPs).** For  
5  
6 the synthesis of SiO<sub>2</sub>@PEI, 20 mL of a suspension of 100 nm FITC-doped silica  
7  
8 nanoparticles (*vide supra*) was added dropwise to the same volume of an aqueous  
9  
10 solution of PEI (10 mg.mL<sup>-1</sup>).<sup>54</sup> After 3 additional hours of mixing, particles were  
11  
12 recovered by centrifugation, washed 2 times in DI water and finally re-suspended in DI  
13  
14 water. For the synthesis of SiO<sub>2</sub>@PEI@SiO<sub>2</sub>,<sup>47</sup> 8 mL of the SiO<sub>2</sub>@PEI solution was  
15  
16 mixed with 5 mL absolute ethanol and 0.8 mL of ammonia and stirred for 10 minutes at  
17  
18 room temperature. Then 0.2 mL of TEOS and 20 μL APTES-FITC was added and the  
19  
20 mixture was allowed to react at room temperature for 16 h. Afterward,  
21  
22 SiO<sub>2</sub>@PEI@SiO<sub>2</sub> nanoparticles were washed with water and ethanol and suspended in  
23  
24 20 mL of water. For the deposition of the second PEI and silica layers, the synthetic  
25  
26 procedure was similar to the previous one, except for the final addition of 200 μL APTES  
27  
28 to obtain SiO<sub>2</sub>@PEI@SiO<sub>2</sub>@PEI@SiO<sub>2</sub>-NH<sub>2</sub> nanoparticles. Next, these particles were  
29  
30 re-dispersed in 5 mL of DMSO, and 8 mg of NHS-PEG<sub>5000</sub>-MAL was added. The  
31  
32 mixture was then stirred at room temperature for 2 hours under anhydrous conditions  
33  
34 before harvesting by centrifugation.  
35  
36  
37  
38  
39  
40  
41  
42  
43  
44

45       **Nanoparticle Characterization.** Particle size distribution, polydispersity index and  
46  
47 zeta potential (ζ) were measured in DI water or cell culture medium (DMEM) using a  
48  
49 ZetaSizer Nano (Malvern Instruments Ltd., Worcestershire, UK). Particles were also  
50  
51 imaged using Transmission Electron Microscopy (TEM) on a FEI Tecnai F<sub>20</sub> U-TWIN  
52  
53 electron microscope (TEM) (FEI Company, Philips, Netherlands). Dynamic Light  
54  
55  
56  
57  
58  
59  
60

1  
2  
3  
4 Scattering (DLS) was used to determine the hydrodynamic diameter of the nanoparticles  
5  
6 in Milli-Q water or in culture medium. The reading was carried out at an angle of 90° to  
7  
8 the incident beam (632 nm). The Contin algorithm was used to analyze the  
9  
10 autocorrelation functions. Fluorescence spectra of the particles suspended in water were  
11  
12 recorded on a Horiba Jobin Yvon fluorescence spectrometer with an excitation  
13  
14 wavelength of 485 nm. Nitrogen (N<sub>2</sub>) sorption measurements were performed at 77K  
15  
16 using an accelerated surface area and porosimetry analyzer with Brunauer-Emmett-Teller  
17  
18 (BET) calculations for the surface area.  
19  
20  
21  
22  
23

24 **Dissolution and Degradation Assays in Buffer and Culture Medium.** To carry  
25  
26 out the *in vitro* degradation experiments in abiotic conditions, a suspension of each type  
27  
28 of PEGylated particles at a 0.4 mg.mL<sup>-1</sup> concentration was left under mild stirring at  
29  
30 37°C in phosphate buffer saline (PBS) 1X or DMEM. The fluorescence intensity of the  
31  
32 medium was analyzed at selected time intervals after centrifugation in a Nanosep® 3kD  
33  
34 centrifugal device to separate particles, that were further used for TEM observation, and  
35  
36 solutions to monitor the proportion of released silane-FITC over time.<sup>39</sup> All experiments  
37  
38 were performed in triplicate.  
39  
40  
41  
42  
43  
44

45 **Cells and Treatments with Nanoparticles.** Normal human dermal fibroblasts  
46  
47 (from Promocell) were grown in DMEM supplemented with FCS (10%), penicillin (100  
48  
49 units.mL<sup>-1</sup>), streptomycin (100 mg.mL<sup>-1</sup>, from Gibco BRL) and fungizone (0.25 mg.mL<sup>-1</sup>,  
50  
51 from Gibco BRL). The culture flasks (75 cm<sup>2</sup>) were kept at 37 °C in 95% humidity and  
52  
53 5% CO<sub>2</sub> atmosphere. At confluence, fibroblasts were removed from cultured flasks by  
54  
55  
56  
57  
58  
59  
60

1  
2  
3  
4 treatment with 0.1% trypsin and 0.02% EDTA. Cells were rinsed, centrifuged and  
5  
6 dispersed in the supplemented DMEM medium. Fibroblasts were used at passage 8 for  
7  
8 the experiments.  
9

10  
11  
12 **Nanoparticle Internalization, Degradation and Release.** The cells were seeded  
13  
14 at a density of 30,000 cells per well in 24-well plate with round glass coverslips at the  
15  
16 bottom of the wells and kept 24 h with culture medium at 37 °C in 95% humidity and 5%  
17  
18 CO<sub>2</sub> atmosphere previous to incubation with 0.4 mg.mL<sup>-1</sup> of the three types of silica  
19  
20 nanoparticles. For fluorescence microscopy, cells were collected at day 1, 2 and 7,  
21  
22 washed three times with PBS 1X, and fixed with 4% paraformaldehyde in PBS (1 h, 4  
23  
24 °C). Staining of the nuclei with DAPI (Invitrogen) was perform via incubation for 15 min  
25  
26 at room temperature and rinsing with HBSS 1X before observation with a fluorescent  
27  
28 microscope (Axio 100, Carl Zeiss). For TEM, cells were fixed at day 1, 2 and 7 using  
29  
30 3.63% glutaraldehyde in a 0.05 M sodium cacodylate buffer with 0.3 M saccharose for 1  
31  
32 h at 4 °C. Samples were washed three times before post-fixing with 2% osmium  
33  
34 tetraoxide for 1 h at 4 °C. Cells were then detached from the culture flasks by scratching  
35  
36 and centrifuged. The pellets were embedded in a 4 mg.mL<sup>-1</sup> collagen hydrogel to ease  
37  
38 sectioning and cellular observations. With this purpose, 50 µL of the type I collagen  
39  
40 solution (in 17 mM acetic acid) was neutralized by 5 µL of PBS and mixed with the  
41  
42 pellet. Mixtures were left for 30 minutes at 20°C to allow collagen gelation. Recovered  
43  
44 hydrogels were fixed with 4% paraformaldehyde in PBS (1 h, 4 °C). Last, cell-containing  
45  
46 collagen hydrogels were dehydrated with an ascending ethanol series ending with  
47  
48  
49  
50  
51  
52  
53  
54  
55  
56

58  
59  
60

1  
2  
3  
4 propylene oxide and embedded in araldite. Ultrathin sections were prepared with an  
5  
6 Ultracut ultramicrotome (Leica, France). Slides were analyzed with a JEOL 1011  
7  
8 electron microscope operating at 120 kV. Images were obtained for at least 10 cells for  
9  
10 each sample.  
11  
12

13  
14  
15 To follow the kinetics of particles degradation and release, continuous cultures were  
16  
17 first performed over 1 week in the presence of  $0.4 \text{ mg}\cdot\text{mL}^{-1}$  silica nanoparticles. After this  
18  
19 delay, the culture medium was removed and cells were rinsed before adding fresh  
20  
21 medium and performing an additional incubation period of 7 days. Fluorescence and  
22  
23 TEM imaging, as well as fluorescence measurements of the whole medium and of its  
24  
25 soluble content were performed as described above. All experiments were performed in  
26  
27 triplicate.  
28  
29  
30  
31

32  
33  
34 **Toxicological Assays.** Cellular metabolic activity of cells in 24-well plate after 2  
35  
36 days of contact with silica particles at concentrations  $0.025\text{-}0.400 \text{ mg}\cdot\text{mL}^{-1}$  and after 1, 2,  
37  
38 7 and 14 days of incubation with  $0.4 \text{ mg}\cdot\text{mL}^{-1}$  silica nanoparticles was evaluated using  
39  
40 Alamar Blue assay (n=6). After incubation, cells were rinsed with medium and incubated  
41  
42 at  $37 \text{ }^\circ\text{C}$  in a humidified 5%  $\text{CO}_2$  air atmosphere for 4 h with a 10% solution of Alamar  
43  
44 blue in phenol red-free culture medium. Absorbance of the medium at 570 nm and 600  
45  
46 nm was recorded with a UV-visible spectrophotometer and the percentage of dye  
47  
48 reduction was calculated. The results were expressed as a percentage of viability assessed  
49  
50  
51  
52  
53  
54  
55  
56  
57  
58  
59  
60

1  
2  
3  
4 in control samples (incubated with no nanoparticles). It is worth mentioning that  
5  
6 incubation of the particles alone with Alamar Blue gave negligible absorbance values.  
7  
8

9  
10 **Statistical Analysis.** Statistical significance of differences was evaluated by a  
11  
12 Wilcoxon-MannWhitney test. This test was chosen instead of Student t test according to  
13  
14 the result of Shapiro-Wilk normality test. A value of  $P < 0.05$  was considered significant.  
15  
16  
17  
18  
19

## 20 21 22 **RESULTS AND DISCUSSION**

23  
24  
25  
26  
27 **Synthesis and Functionalization of Nanostructured Silica Particles.** Silica  
28  
29 nanoparticles with different internal structures were synthesized and characterized using  
30  
31 transmission electron microscopy (TEM), dynamic light scattering (DLS) and zeta  
32  
33 potential measurements. PEGylated BSA-coated silica nanoparticles, PEI-coated silica  
34  
35 nanoparticles and hollow mesoporous silica nanoparticles were named as BSNPs, PSNPs  
36  
37 and HSNPs respectively.  
38  
39  
40  
41

42  
43 Fairly uniform BSNPs were prepared by using a modified Stöber method in the  
44  
45 presence of BSA. As shown in the TEM images (**Figure 1a,d**), the BSNPs are spherical in  
46  
47 shape with a mean diameter of ~45 nm. They exhibit a well-contrasted core-shell structure  
48  
49 suggesting that they consist of a silica-rich layer coating a BSA-rich internal domain.<sup>50</sup>

**Figure 1** : TEM images of the as-prepared PEGylated fluorescent silica nanoparticles: (a, d) BSNPs; (b, e) PSNPs and (e, f) HSNPs.

**Table 1** : Mean diameter  $D_m$  from DLS and TEM, Zeta potential  $\zeta$  in deionized water and culture medium.

	$D_m$ DLS	$D_m$ TEM	$\zeta$ water	$\zeta$ medium
	(nm)	(nm)	(mV)	(mV)
BSNPs	$109 \pm 6$	$44 \pm 2$	$-15 \pm 1$	$-8 \pm 1$
PSNPs	$190 \pm 6$	$176 \pm 4$	$-8 \pm 1$	$-5 \pm 1$
HSNPs	$310 \pm 10$	$261 \pm 7$	$-11 \pm 1$	$-7 \pm 1$

DLS measurements in deionized water indicated a two-fold increase in the mean diameter  $D_m$ , compared to TEM, suggesting that some aggregation occurred, although to a limited

1  
2  
3  
4 extent (**Table 1** and **Figure S1**). This aggregation was confirmed by performing a DLS  
5  
6 analysis of a BSNPs suspension just after sonication, yielding to a  $D_m$  value of  $44 \pm 10$   
7  
8 nm (**Figure S1**). The successful functionalization process with amine and then PEG  
9  
10 groups was evidenced by size and  $\zeta$  potential modifications (**Table S1** in ESI): whereas  
11  
12 the as-prepared BSA@SiO<sub>2</sub> exhibited a strongly negative  $\zeta$  value, APTES grafting led to  
13  
14 a slightly positive  $\zeta$  value due to ammonium groups. This was correlated with an  
15  
16 increase in the  $D_m$  value as obtained by DLS, in agreement with the decrease of  
17  
18  $\zeta$  absolute value leading to a lower colloidal stability. After PEG grafting, the  $D_m$  value  
19  
20 obtained by DLS decreased, due to the ability of the polymer coating to limit BSNPs  
21  
22 aggregation, and the  $\zeta$  value became negative, due to the reaction of some of the surface  
23  
24 amine groups with NHS-PEG<sub>5000</sub>-MAL.  
25  
26  
27  
28  
29  
30  
31  
32

33 PSNPs were obtained from plain silica nanoparticles by a layer-by-layer method  
34  
35 using branched PEI (25 kDa). Starting from ~100 nm Stöber nanoparticles, two  
36  
37 successive sequences of PEI deposition/silica coating were performed. Variations in  
38  
39  $\zeta$  value occurred as expected, *i.e.*  $\zeta > 0$  for outer PEI layer and  $\zeta < 0$  after silica  
40  
41 deposition (**Table S1** in ESI). Again, APTES grafting turned the particle surface positive  
42  
43 while PEG conjugation ultimately led to negatively-charged PSNPs in deionized water  
44  
45 (**Table 1**). The accompanying modifications of hydrodynamic diameter, as obtained by  
46  
47 DLS, are difficult to analyze in details in terms of size variations as they are the result of  
48  
49 PEI conformation on the particle surface, silica layer thickness as well of the aggregation  
50  
51 tendency of the different systems. Nevertheless TEM imaging (**Figure 1b**) provides a  $D_m$   
52  
53  
54  
55  
56  
57  
58  
59  
60

1  
2  
3  
4 value of  $\sim 175$  nm and therefore an overall coating thickness of  $\sim 35$  nm, clearly  
5  
6 evidenced at higher magnification (**Figure 1e**).

7  
8  
9  
10 Hollow HSNPs were prepared by etching 100 nm-Stöber nanoparticles following the  
11  
12 method proposed by Chen et al.<sup>53</sup> TEM imaging clearly showed that HSNPs have a  
13  
14 spherical morphology and uniform particle size  $\sim 260$  nm, with a porous shell thickness  
15  
16 of  $\sim 50$  nm and a highly porous core, although a central denser region, corresponding to  
17  
18 unreacted part of the starting Stöber particles, could sometimes be distinguished (**Figure**  
19  
20 **1c,f**). The overall synthetic process was also followed by DLS and  $\zeta$ -metry (**Table S1**),  
21  
22 showing that despite the fact that APTES-modified intermediates are particularly prone to  
23  
24 aggregation ( $D_m = 780 \pm 40$  nm), the PEG coating efficiently enhances the colloidal  
25  
26 stability of final HSNPs particles ( $D_m = 310 \pm 10$  nm in deionized water compared to  $260$   
27  
28  $\pm 7$  nm from TEM) (**Table 1**). Nitrogen adsorption-desorption isotherm measurements  
29  
30 indicated that the HSNPs had a relatively high specific surface area of *ca.*  $550 \text{ m}^2 \cdot \text{g}^{-1}$  and  
31  
32 a well-defined mean pore size of  $3.9$  nm (**Figure S2**).

33  
34  
35  
36  
37  
38  
39  
40  
41  
42 Altogether, when the three types of particles are compared, their size, as obtained  
43  
44 from both DLS in deionized water and TEM, vary in the order HSNPs > PSNPs >  
45  
46 BSNPs. In terms of surface properties, their zeta potential in deionized water (pH 6.5) is  
47  
48 always negative and follows the PSNPs > HSNPs > BSNPs evolution. Interestingly, the  
49  
50 same order of  $\zeta$  values is found for  $\text{NH}_2$ -grafted particles, suggesting that the PEG  
51  
52 coupling occurred in a similar extent for the three systems. This order is preserved over  
53  
54  
55  
56  
57  
58  
59  
60

1  
2  
3  
4 the whole pH 2-11 range with apparent isoelectric points (IEP) of ca. 4.5, 5.5 and 6.2 for  
5  
6 BSNPs, HSNPs and PSNPs, respectively (**Figure S3**). It is also maintained in cell culture  
7  
8 medium although with some minor variations between the different particles. A  
9  
10 systematic increase in  $\zeta$  values compared to deionized water is observed that very likely  
11  
12 indicates the surface adsorption of positively-charged proteins present in FCS-enriched  
13  
14 DMEM (**Table 1**).<sup>55</sup> The incorporation of FITC within the different nanoparticles was  
15  
16 checked by fluorescence measurements. As shown in **Figure S4**, the FITC-doped silica  
17  
18 nanoparticles gave rise to a strong emission, with no significant shift in the maximum  
19  
20 wavelength compared to the dye alone. However, at a constant particle concentration, the  
21  
22 signal intensity varied from one particle type to the other. Such a difference may reflect  
23  
24 various silica contents in the nanoparticle structures. For instance, the lowest intensity  
25  
26 was obtained for BSNPs, *i.e.* hybrid nanoparticles containing large amounts of BSA.  
27  
28 However, other processes such as FITC fluorescence variations due to different dye  
29  
30 environment and mobility may also contribute to these differences.<sup>56</sup>

41 **Behaviour of Nanoparticles in Buffer and Cell Culture Medium.** To investigate  
42  
43 the influence of the internal structure of silica nanoparticles on their degradation in  
44  
45 abiotic (*i.e.* cell-free) media, TEM imaging and monitoring of the kinetics of silica  
46  
47 dissolution was first performed in a PBS buffer (pH 7.4) at 37 °C over 2 weeks. After one  
48  
49 week, all nanoparticles showed a clear tendency to form aggregates under TEM imaging  
50  
51 conditions (**Figure 2**). For BSNPs, the core-shell structure is overall preserved but some  
52  
53 particles appear to have grown in size and the contrast between the inside and outside  
54  
55  
56  
57  
58  
59  
60

1  
2  
3  
4 parts has increased compared to the initial particles. For PSNPs, the outer silica shell is  
5  
6 less well-defined. No further evolution could be evidenced for these two sets of particles  
7  
8 after one additional week, except for a higher tendency to aggregate. In parallel, the  
9  
10 internal structure of HSNPs does not appear much modified after one week but some  
11  
12 deformed particles are observed. After two weeks, they have turned into highly porous  
13  
14 particles with a weaker contrast between the shell and the core parts, some of them being  
15  
16 particles with a weaker contrast between the shell and the core parts, some of them being  
17  
18 obviously fractured.

42 (a-c) one and (d-f) two weeks.  
43  
44

45

46

47 The dissolution of these different particles was also studied in the DMEM cell  
48 culture medium at 37 °C (**Figure 3** and **Figure S5** for higher magnification images). For  
49 BSNPs, after one week, some particles have grown in size while others are broken. Only  
50 small fragments could be recovered after 2 weeks. For PSNP samples after 1 week, the  
51

55  
56  
57  
58  
59  
60

1  
2  
3  
4 outer coating has a shallow appearance and is decorated with porous particles 10-30 nm  
5  
6 in diameter. Strikingly, after two weeks, two populations of particles are observed: larger  
7  
8 ones, *ca.* 100-150 nm in diameter, exhibiting a dense core and a porous shell, and smaller  
9  
10 ones, 20-50 nm in size, with a porous internal structure resembling that of  
11  
12 previously-observed decorating particles. Such an evolution would suggest dissolution of  
13  
14 the silica material constituting PSNPs shell and core and its reprecipitation into smaller  
15  
16 particles. To support this hypothesis, a more detailed analysis by TEM of the kinetics of  
17  
18 degradation of these nanoparticles was performed, evidencing that the progressive  
19  
20 appearance of the porous external small particles was correlated with a decrease in the  
21  
22 density of the largest ones (Figure S6)

30

48 culture medium after (a-c) on week and (d-f) two weeks.

49  
50  
51  
52  
53 For HSNPs, TEM images after 1 week are highly reminiscent of those previously  
54  
55 obtained in PBS after 2 weeks. Within two weeks, after centrifugation and washing, only  
56  
57

1  
2  
3  
4 a few of these nanoparticles could be recovered with an intact morphology and imaged.  
5  
6 These particles seem to have grown in size and the shell and core particle appear denser  
7  
8 and separated by a highly porous, if not empty, region. Hence, overall, the culture  
9  
10 medium appears to speed up the degradation process of all particles compared to PBS at a  
11  
12 similar pH.  
13  
14  
15

16  
17  
18 In parallel, the dissolution rate of the particles in culture medium was investigated  
19  
20 through the monitoring of the fluorescence of the solution after centrifugation and  
21  
22 filtration. Because these steps eliminate silica particles and since FITC forms a stable  
23  
24 covalent bond with the silica network, the fluorescence signal can only correspond to  
25  
26 FITC-silane or soluble FITC-polysiloxane molecules released upon silica dissolution.<sup>39</sup>

4 **Figure 4** : Evolution of the content of the culture medium over 2 weeks in the presence  
5  
6 of silica nanoparticles as monitored by the fluorescence intensity of FITC-labelled  
7  
8 soluble forms of silica.  
9

10  
11  
12 After 1 day, more than 50 % of the BSNPs particles are dissolved and the maximum  
13  
14 dissolution of 65 % is reached after 1 week (**Figure 4**). For HSNPs, a similar rapid  
15  
16 dissolution is observed but the maximum dissolution of 40 % is reached after 1 week.  
17  
18 PNSPs dissolve much more slowly (*ca.* 10 % after 1 day) and, after 2 weeks, only 30 %  
19  
20 of the initial fluorescent silanes are present in a soluble form. These data confirm the low  
21  
22 stability of BSNPs in DMEM. For PNSPs, the low degradation rate and extent are in  
23  
24 favor of the proposed mechanism of progressive reprecipitation of the soluble forms  
25  
26 originating from the shell and then core particle dissolution. HSNPs represent an  
27  
28 intermediate case, with fast initial dissolution rate followed by a plateau and low  
29  
30 dissolution extent, suggesting that some reprecipitation reactions also occur, but in a less  
31  
32 efficient manner than in PNSPs

41

42 **Nanoparticles Behaviour in the Presence of Fibroblasts.** To study the possible  
43  
44 impact of nanoparticle structure and degradation on cell viability, NHDF cells were used  
45  
46 as model organisms and the Alamar Blue method, which measures the mitochondrial  
47  
48 activity of the cells, was selected to monitor the cellular response to nanoparticles  
49  
50 (**Figure 5**). After a 48 h incubation period, in all the range of concentrations tested,  
51  
52 BSNPs and HSNPs did not show a significant toxicity while PNSPs induced an initial  
53  
54  
55  
56  
57  
58  
59  
60

slight reduction of cell viability in all conditions, down to 75% of cell viability at a 400  $\mu\text{g}\cdot\text{mL}^{-1}$  dose. However, at this concentration, NHDFs recovered from PSNPs cytotoxicity after 1 week.

**Figure 5:** (a) Alamar blue assay results for NHDF cells after incubation with silica nanoparticles at various concentrations (25-400  $\mu\text{g}\cdot\text{mL}^{-1}$ ) for 2 days. (b) Alamar blue assay results for NHDF cells after incubation with 400  $\mu\text{g}\cdot\text{mL}^{-1}$  of silica nanoparticles at various time intervals (1-14 days). The data represent six separate experiments. Mean values  $\pm$  SD. \* $P < 0.05$  versus a control group.

Referring to the dissolution kinetics shown in **Figure 4**, neither BNSPs nor their degradation products have significant cytotoxic effects. PSNPs are cytotoxic on the short term, a period where the outer layers are slowly dissolving. This result can be correlated to previous reports showing that the presence of an external silica layer decreases the toxicity of poly-lysine-coated gold nanoparticles.<sup>57</sup> On this basis, it can be suggested that the initial dissolution of the silica layers leads to the release of cytotoxic PEI. However,

1  
2  
3  
4 the redeposition of smaller silica particles on PNSPs surface, as observed in **Figure 3**,  
5  
6 may circumvent this effect on the longer term.  
7  
8  
9

10 The particle uptake by NHDFs in culture medium was followed by fluorescent  
11 microscopy using the same silica concentration ( $400 \mu\text{g}\cdot\text{mL}^{-1}$ ). After 24 h, silica  
12 nanoparticles associated with cells were evidenced but many of them appeared to be  
13 attached to the cell membrane as aggregates (**Figure S7**). With time, these aggregates  
14 became less visible and the fluorescent signal appeared confined within the cell interior,  
15 with a higher intensity for PSNPs and HSNPs compared to BSNPs after 2 weeks (**Figure**  
16

13  
14  
15  
16  
17

18  
19 However, to fully ascertain particle internalization, TEM imaging was performed  
20  
21 (**Figure 7** and **Figure S8** for lower magnification images). After 1 week, BSNPs are  
22  
23 sparingly found as intracellular aggregates of particles that have decreased in size as an  
24  
25 apparent consequence of shrinking after core material removal. PSNPSs and HSNPs are  
26  
27 more easily distinguished both outside and inside the cells. The former appear as plain  
28  
29 particles decorated with smaller particles. For HSNPs the shell has grown in thickness  
30  
31  
32 while the internal structure has started to degrade, as previously observed in DMEM after  
33  
34  
35  
36  
37 2 weeks.

**Figure 7** : TEM images of NHDF cells after (a-c) 1 week and (d-f) 2 weeks of contact with  $400 \mu\text{g.mL}^{-1}$  silica nanoparticles.

**Degradation and Release Kinetics.** The kinetics of degradation and release of the nanoparticles was further studied by keeping NHDFs in contact with silica nanoparticles for 1 week after which the cells were rinsed off the remaining external particles and incubated in fresh culture medium for an additional week. Over the first 24 h, for all particles, the total fluorescence of the solution is initially very low and then increase progressively up to *ca.* 80 % of the intensity of the initial particle suspension (**Figure 8a**). This can be correlated with fluorescence optical imaging indicating that particles first adhere on the cell surface (decreasing the amount of free particles in solution) and are then progressively detached. Yet a decrease in total fluorescence intensity is observed after 48 h, that may reflect enhanced particle internalization.<sup>39</sup> Considering the release of soluble forms in the culture medium, the kinetics profiles are very similar to those obtained in the absence of NHDF. However, the maximum apparent dissolution ratio is

1  
2  
3  
4 significantly smaller for BSNPs (50 % compared to 60 % without NHDF) and PSNPs (20  
5  
6 % compared to 30 %). This would suggest that a fraction of the soluble forms is retained  
7  
8  
9 by the cells.

27  
28  
29 **Figure 8:** Evolution of the content of the NHDF cells culture medium as monitored by  
30 the fluorescence intensity of FITC-labelled condensed and soluble forms of silica (filled  
31 symbols) and soluble forms only (open symbols) (a) over 1 week in the presence of silica  
32 nanoparticles and (b) over 1 additional week in a fresh medium.

33  
34  
35  
36  
37  
38  
39  
40 After cell rinsing and incubation in a fresh, particle-free medium for an additional  
41 week, intracellular nanoparticles were more difficult to observe in TEM imaging fields  
42  
43 (Figure 7d and Figure S8). When this was possible, we did not evidence any clear  
44  
45 change for BSNPs compared to day 7. PSNPs have significantly decreased in size and  
46  
47 exhibit a porous structure. No well-defined HSNPs could be observed after this period  
48  
49 and only fragments could be imaged that may originate from their full dissociation. In  
50  
51 parallel, the total FITC fluorescence intensity in the culture medium, initially equal to  
52  
53  
54  
55  
56  
57

1  
2  
3  
4 zero because of the incubation in a fresh medium, increased with time (**Figure 8b**). At  
5  
6 the end of this additional period, almost all the initial fluorescence intensity (as calculated  
7  
8 by adding 1 week values obtained from Figure 8a and 2 weeks values from Figure 8b)  
9  
10 was recovered for the three kinds of particles, indicating that a negligible fraction of  
11  
12 silica remains inside the cells, in agreement with TEM experiments. However, whereas  
13  
14 BSNPs and HSNPs were almost fully released in a soluble form, more than 30 % of  
15  
16 PSNPs were externalized in a colloidal form.  
17  
18  
19  
20  
21  
22

23 **Degradation Pathways.** BSNPs initially show TEM-contrasting internal features  
24  
25 that suggest that they consist of a protein-rich interior surrounded by a silica-rich coating.  
26  
27 In PBS, these particles grow in size, with an apparent leakage of the core material, the  
28  
29 process being accelerated in culture medium. Finally, particle degradation occurs, leaving  
30  
31 much smaller empty particles. A similar process seems to occur within the NHDF cells,  
32  
33 although at a higher rate. Additional experiments performed using BSNPs incorporating  
34  
35 FITC-labelled BSA showed that, after one week of contact with NHDF, the protein was  
36  
37 hardly detectable within or at the vicinity of the cells whereas silica was still present in  
38  
39 large amounts (compare **Figure S9** with **Figure 6a**). The most likely explanation of these  
40  
41 evolutions is that water penetration within the particle leads to the swelling of the BSA  
42  
43 core, disruption of the silica shell and leakage of the protein (**Figure 9**). As suggested  
44  
45 earlier, the enzymatic degradation of BSA in the intracellular compartment may  
46  
47 contribute to accelerate these processes.  
48  
49  
50  
51  
52

**Figure 9:** Schematic representation of the degradation pathways of BSNPs, HSNPs and PSNPs in DMEM culture medium.

For HSNPs, silica dissolution in PBS apparently occurs first from the shell, resulting in particles that are almost uniformly porous except for the central part and are prone to

1  
2  
3  
4 deformation and breaking (**Figure 9**). The same process occurs in culture medium but  
5  
6 after two weeks, the only remaining particles exhibit a highly contrasted shell and a  
7  
8 denser central part, separated by a nearly empty corona. Such structures were also  
9  
10 observed after one week within cells and evolved towards a complete disintegration after  
11  
12 2 weeks. While the initial shell dissolution should be favored by its mesoporous structure,  
13  
14 the following process can be explained considering the dissolution of the more porous  
15  
16 (*i.e.* more soluble) silica corona located between the shell and the core particle and its  
17  
18 reprecipitation on these two denser (*i.e.* less soluble) regions, based on the Ostwald  
19  
20 ripening principle.  
21  
22  
23  
24  
25  
26  
27

28 Overall BSNPs and HSNPs evolve more rapidly but along similar pathways in PBS,  
29  
30 in DMEM and in the intracellular space. When experiments in buffer and culture medium  
31  
32 are compared, pH and total silica concentration are similar. Ionic strength of DMEM is  
33  
34 0.13 M, being therefore comparable with the 0.16 M value for PBS 1X. However,  
35  
36 DMEM supplemented with FCS contains several bio-organic components (amino acids,  
37  
38 proteins) that can interact with silica. For instance, it was shown that histidine and  
39  
40 phenylalanine could promote silica dissolution.<sup>28</sup> Extending this discussion to  
41  
42 intracellular compartments is indeed difficult as their composition is complex and  
43  
44 variable. Nevertheless it is worth pointing out that lysosomes were reported to contain a  
45  
46 high fraction of free amino acids.<sup>58</sup> It is also interesting to note that intracellular  
47  
48 compartments that are involved in nanoparticle trafficking are reported to be slightly  
49  
50 (endosomes) to significantly (lysosomes) acidic so that a decrease of silica dissolution  
51  
52  
53  
54  
55  
56  
57  
58

1  
2  
3  
4 rate could be expected compared to neutral conditions of PBS/DMEM medium. While  
5  
6 this point would require a detailed investigation of the particle structural modification in  
7  
8 the first hours of the internalization process, our experiments suggest that the difference  
9  
10 in pH conditions is not of primary importance for their long-term fate.  
11  
12  
13

14  
15 However, another important point must be taken into consideration. The full release  
16  
17 of silicon species from the cells to the medium clearly demonstrates that the products of  
18  
19 the intracellular dissolution reaction can be externalized in a continuous manner. Hence,  
20  
21 whereas the extent of particle dissolution in solution is limited by the silica limit of  
22  
23 solubility, the conditions of degradation within intracellular compartments can be  
24  
25 compared to that of an open reactor, although previous reports evidenced that the  
26  
27 exocytosis extent was dependent on the amount of silica in the medium.<sup>59</sup> This can  
28  
29 explain the difference evidenced for PNSPs in DMEM and within NHDFs. In the culture  
30  
31 medium, a decrease in initial particle size is observed after 1 week and smaller particles  
32  
33 are clearly visible at their vicinity (**Figure 9**). This suggests that the outer PEI/silica  
34  
35 layers first dissolve but, because PEI is known to promote silica precipitation,<sup>60</sup> the  
36  
37 released soluble silica species and the polyelectrolyte chains can react together to form  
38  
39 these new particles, as previously suggested.<sup>35</sup> In a second stage, the largest particles turn  
40  
41 porous, indicating that further dissolution occurs and feeds the growth of the external  
42  
43 smaller particles. Noticeably, within the cells, these additional particles are hardly  
44  
45 distinguished although the transformation from plain to porous large particles is also  
46  
47 observed. This result nicely correlates with our observation that, whereas BSNPs and  
48  
49  
50  
51  
52  
53  
54  
55  
56  
57  
58  
59  
60

1  
2  
3  
4 HSNPS are almost exclusively released in soluble forms during the second week, almost  
5  
6 30 % of PNSPs are externalized in a colloidal form that may correspond to the  
7  
8 newly-formed silica nanoparticles that are small enough to be expelled.  
9  
10

## 11 12 13 14 15 **CONCLUSION**

16  
17 By following the evolution of silica nanoparticles with different internal nanostructures in  
18  
19 solution and within normal human dermal fibroblasts, we show that their degradation  
20  
21 pathways are very similar in all conditions although the precise composition of the  
22  
23 medium can impact on the kinetics of the degradation. This supports previous  
24  
25 assumptions that within such cells silica nanoparticles undergo a hydrolytic degradation  
26  
27 process, related to silica chemistry, and not a biodegradation route, that would involve a  
28  
29 specific biological activity. From a more fundamental point of view, these data contribute  
30  
31 to the on-going debate on the role of silicon and its associated biochemical pathways in  
32  
33 mammalian cells, that have a great importance to understand and predict the *in vivo* fate  
34  
35 of silica biomaterials. From a practical perspective, this implies that the intracellular fate  
36  
37 of silica-based nanomaterials can be controlled and predicted on the basis of  
38  
39 physico-chemical considerations unless they incorporate bio-responsive functions.
