Preserving the spin transition properties of iron-triazole coordination polymers within silica-based nanocomposites†

H. Voisin,^{‡a} C. Aimé,^{id a} A. Vallée,^{§a} A. Bleuzen,^{id b} M. Schmutz,^c G. Mosser,^{id a} T. Coradin,^{id *a} and C. Roux^{*a}

One dimensional iron(II) coordination polymers formed from 1,2,4-triazole bridging ligands are a unique class of spin-crossover materials (SCO). The integration of those coordination polymers into devices for practical applications remains a major challenge. Using a nanocomposite approach based on the control of coordination polymer interactions with chemically engineered silica particles, we show that we can achieve *in situ* gelation, while preserving the SCO properties of the solid state. Tuning the interface between the two phases of a composite provides a unique way to synergistically adjust the material's structure and the cooperativity associated with its transition properties. The strategy described here should allow for bridging the gap between soft and crystalline functional inorganic materials.

Introduction

Spin crossover (SCO) systems are fascinating materials that can be switched from one stable electronic state to another by external stimuli making them very promising for molecular electronics.^{1,2} In particular, 1,2,4-triazoles are known as bridging ligands that form one-dimensional iron(II) coordination polymers.^{3–6} These compounds exhibit cooperative spin transitions between low-spin (LS) and high-spin (HS) states around room temperature, with large thermal hysteresis and a well-pronounced thermochromic effect.⁷ $[\text{Fe}(\text{RTrz})_3][\text{X}] \cdot x\text{H}_2\text{O}$ polymers (RTrz = 4-substituted-1,2,4-triazole, X = counter anion and $x\text{H}_2\text{O}$ stands for non-coordinated water molecules) form a unique class of spin-crossover materials. This is due to their synthetic versatility and the sensitivity of the environment of the iron sites within polymer chains of different lengths and structures that can be diverted to tune the spin-crossover properties.^{8–12} Indeed, the SCO temperature and cooperative

character can be tuned by the nature of the substituent on the triazole ligand, as well as by playing with the hydration solvent.⁵ In addition, the counter-ion effect has been investigated by different groups.^{3,9,11,13–15} Sulfonate derivatives show capabilities for hydrogen bonding with the lattice water molecules that is responsible for the stabilization of the low spin state. From this solvated state, the removal of water molecules induces the transition to the high-spin state.³

One of the main current challenges in spin crossover research is to integrate SCO compounds into devices suitable for practical applications in micro- and nanotechnology. An important issue is to ensure the preservation of the bistability and the cooperative spin transition properties of the compounds at the nanoscale.^{16–18} Different routes have been developed to obtain technologically useful materials including films, multilayers, liquid crystals and nanoparticles.^{13,19–22} Gels have also been proposed as an alternative option to obtain useful materials.²³ From this perspective, metallogels^{24,25} can be considered as soft matter states of inorganic coordination polymers that are otherwise mostly obtained as powders. This state allows for their application in a wide range of areas, from catalysis to medicine.^{26–30} The successful integration of SCO within a gel must satisfy two requirements: the integration of anions inducing a spin-crossover around room temperature and the presence of gelators. In this context, triazole ligands functionalized with long alkyl chains have been used to obtain gelators.^{31–34} These two features could also be associated within a unique molecular component, using lipophilic sulfonate counter-anions to drive the formation of supramolecular gels.³⁵ Alternatively, a series of triazole ligands bearing large lipophilic

substituents were used to form one-dimensional coordination polymers that could further assemble in a gel phase.^{10,13} These works have evidenced the importance of the dimensional structure (two- or three-) in the cooperativity effect associated with the spin transition, where the temperature dependence of the high spin molar fraction strongly depends on intermolecular interactions.³⁶

Alternatively, coordination clusters can be incorporated within matrices to obtain nanocomposites. Such approaches allow tuning the cooperativity between spin-active sites that should be strongly connected to ensure an abrupt spin transition.^{18,37–39} Interestingly, Raza *et al.* showed that a thin shell of SiO₂ formed around a SCO nanoparticle allowed the persistence of a hysteretic behavior due to the rigidity of the matrix, while enhanced cooperativity could be achieved by varying the interparticle distances.⁴⁰ Other works reported the engineering of silica thin films with controlled porosity, doped with spin crossover particles.^{21,41–44} However, in the above-described strategies, the spin transition properties are usually modified compared to the solid-state systems. To address this point, we have developed here a nanocomposite approach where a coordination polymer in suspension is associated with surface-modified silica nanoparticles. Silica nanoparticles serve as chemically versatile platforms to adjust the SCO properties, while providing reticulation nodes for gelation. In particular, negatively charged sulfonate groups grafted at the surface of silica particles were selected to act as counterions of [Fe(ATrz)₃]²⁺ chains (noted hereafter as Fe/ATrz with ATrz = 4-amino-1,2,4-triazole, Fig. 1a) and further fulfilled the requirements for SCO properties and gelation. Self-standing gels were obtained and fully characterized, highlighting the multiscale complexity of the spin crossover

phenomenon. This work shows that it is possible to establish a clear relationship between structural percolation and cooperativity effects. This sheds light on the fact that such a nanocomposite approach allows for bridging the gap between soft and crystalline inorganic materials.

Results and discussion

Preparation and properties of a particle-free system (Fe/ATrz/SO₄ suspension)

In a first step, the possibility of obtaining a metastable gel with an abrupt and reversible spin transition was explored with Fe²⁺ and simple RTrz derivatives (HTrz or ATrz). If we exclude the nanoparticle syntheses by the reverse-micelle method, a single paper describes the formation of metallogels based on [Fe(ATrz)₃](2ns)₂ (2ns = 2-naphthalenesulfonate) in *N,N*-dimethyl-formamide solvent at a high iron concentration of [Fe²⁺] = 0.1 M.⁴⁵ We hypothesized that a careful selection of iron(II) salts should allow for the gelation of other polar solvents from HTrz or ATrz. Since it is difficult to pinpoint a general strategy to obtain a metallogel in polar solvents, a preliminary screening was performed for different polar solvents (glycerol, ethylene glycol, water and ethanol) with various Fe²⁺ salts (such as FeBr₂, Fe(BF₄)₂ and Fe(SO₄)·7H₂O) at high iron concentration ([Fe²⁺] = 0.1 M) and a molar RTrz/Fe²⁺ ratio of 3/1. This ratio is the stoichiometric ratio of the ideal coordination polymer [Fe(RTrz)₃]²⁺. These preliminary tests led to three different systems: (i) amorphous gels with poorly reversible spin transition properties in polyol solvents (for example [Fe(HTrz)₃]Br₂ in glycerol). These gels are formed from pink solutions indicative of the presence of low spin species before gelation (Fig. S1a, ESI†). (ii) Pink crystalline precipitates were obtained in ethanol or water (for example [Fe(ATrz)₃]SO₄ in water) (Fig. S1b, ESI†) exhibiting the same reversible SCO properties as in the solid state. (iii) A stable white suspension (denoted as Fe/ATrz/SO₄) was achieved only using FeSO₄ in combination with ATrz in a mixture of ethylene glycol (EG) and water in a 9:1 volume ratio (Fig. 1b). Noticeably, the molar ATrz/Fe²⁺ ratio used for this synthesis was increased to 6:1 in order to promote the expected compound, [Fe(ATrz)₃]SO₄,^{45,46} due to the strong complexing ability of SO₄^{2−} anions for Fe(II) ions. Upon ageing, the initial Fe/ATrz/SO₄ viscous suspension changed from white to pink. In addition, we observed a color change (pink to white) upon heating that was reversible upon cooling. Before investigating the possibility of making a gel out of this system *via* a composite strategy, we characterized the properties associated with this observed color change in detail.

After 9 days of ageing, the thermochromic behavior of the suspension could be followed by visible light absorption measurements (Fig. 2). As for all other thermal experiments, we discuss data obtained during the second thermal cycle to get rid of the synthesis thermal history of the sample. At room temperature (293 K), the UV-Vis absorbance spectrum of the pink sample showed a band at λ ca. 520 nm with a diffusion background. The latter is due to light scattering effects and hampers the exact determination of the band characteristics.

Fig. 1 Schematic representation of (a) a coordination polymer chain, and of the synthesis route for (b) the Fe/ATrz/SO₄ suspension and (c) the NP-SiSO₃@Fe/ATrz/SO₄ composite.

Fig. 2 Evolution of the UV-Visible spectrum of the Fe/ATrz/SO₄ suspension aged for 9 days along a second temperature cycle in the heating (line) and cooling (symbols) modes (293–343 K in steps of 10 K, scan rate about 5 K min⁻¹). The inset shows the visual aspect of the samples.

By subtracting the diffusion background, the maximum band and the molar extinction coefficient could be estimated to be $\lambda = 532$ nm and $\epsilon = 80$ cm⁻¹ mol⁻¹ L, respectively corresponding to the d-d electronic transition of the iron ions in the low spin state (¹A_{1g} → ¹T_{2g}).⁴⁷ It is worth mentioning that the molar extinction coefficient refers to a repeat unit of the polymer (*i.e.* not to a polymer molecule). This band started to fade at 330 K along with the discoloration of the sample and reached a minimum at 340 K, when the sample was completely white indicative of the high spin state. Cooling the sample back to room temperature led to the immediate reappearance of the peak at 520 nm with the sample turning pink again. This indicates a reversible spin change.

Differential scanning calorimetry (DSC) was used to further investigate the SCO phenomenon and to follow its evolution during the ageing of the suspension (Fig. 3a). At a rate of 5 K min⁻¹, no thermal event could be evidenced for the suspension aged for one day after mixing that remained white. However, a small broad endothermic transition was found after three days around $T_{\text{max}}^{\uparrow} = 316$ K, accompanied upon cooling by a small broad exothermic peak around $T_{\text{max}}^{\downarrow} = 302$ K. Over the next six days, the peaks grew in intensity and became narrower. An endothermic peak at $T_{\text{max}}^{\uparrow} = 325$ K and an exothermic peak at $T_{\text{max}}^{\downarrow} = 310$ K were observed respectively in warming and cooling modes. This is indicative of a first-order phase transition. The peak separation suggests a hysteresis loop width of 15 K. After 20 days, the DSC peaks were shifted towards higher temperatures ($T_{\text{max}}^{\uparrow} = 327$ K, $T_{\text{max}}^{\downarrow} = 312$ K) but the hysteresis loop width was not significantly modified. This is consistent with a cooperative spin crossover behavior. Interestingly, the hysteresis loop occurred at lower temperature than those previously reported in the literature; typically $T_{\text{max}}^{\uparrow} = 346$ K, $T_{\text{max}}^{\downarrow} = 319$ K for a hysteresis of 27 K for the hydrated complex.⁴⁸ This difference in T_{max} may be attributed to a solvent effect (water vs. H₂O/EG).

Parallely, the structural evolution of the suspension upon ageing was monitored by X-ray powder diffraction (XRPD) (Fig. 3b). One day after synthesis, the diffractogram showed two broad peaks centered at $2\theta = 25^\circ$ and 42° , indicative of an amorphous phase. Later on, several well-defined diffraction

Fig. 3 Evolution of (a) the DSC curve over a second heating/cooling cycle at 5 K min⁻¹ and (b) XRPD diffractograms of the Fe/ATrz/SO₄ suspension upon ageing.

peaks emerged and their intensities relative to the background increased with time until a maximum was reached after nine days. Yet the broad peaks were still clearly visible and the low-angle component increased in intensity with ageing. This suggests either the co-existence of two distinct phases of different crystallinity or a single phase exhibiting a semi-crystalline behavior. Variable temperature XRPD analyses were performed on the suspension aged for 9 days. Most of the diffraction peaks obtained at 298 and 353 K overlapped in the 2θ range of 7 – 60° (Fig. S2, ESI†) except in the 20 – 35° range (Fig. 4a). The diffraction peaks underwent a shift towards smaller 2θ values upon heating that was fully reversible upon cooling. A more detailed variable temperature analysis was performed by recording XRPD patterns between 298 K and 348 K in steps of 5 K (mean scan rate of 1 K min⁻¹) focusing on the diffraction peaks at 25.3° (present at 353 K) and 26.2° (present at 298 K) for which this shift was particularly significant. As shown in Fig. 4b, the intensity of the peak at 26.2° decreased with increasing temperature until the peak disappeared at 328 K. Upon cooling, it reappeared at 318 K and reached its maximal intensity at 308 K. In contrast, the peak at 25.3° was evident from 318 K and raised in intensity up to 348 K. Its intensity started to decrease upon cooling back to 318 K and disappeared at 308 K. This indicates the coexistence of two crystalline phases associated with a reversible first order spin-transition (LS/HS), in fair agreement with the DSC data.

Further information was obtained using electron microscopy (Fig. 5). After 9 days of ageing, SEM images revealed

Fig. 4 Evolution of the XRPD diffractogram of the Fe/ATrz/SO₄ suspension aged for 9 days (a) in a large range of 2θ at 298 K before and after heating, and at 353 K, (b) in the restricted 2θ range of 24.5–27° upon a second cycle of heating (lines) and cooling (dashed lines) (between 298 and 348 K in steps of 10 K; mean scan rate = 1 K min⁻¹).

the general aspects of the crystalline phase, consisting predominantly of needle-shaped particles typically 1 μm long and 100 nm wide forming a porous network. Cryo-TEM imaging allowed for the clear observation of an amorphous phase appearing as a grayish matrix embedding the needle-like particles. These observations, together with the well-established correlation between the extent of the spin transition and the crystallinity of the sample, suggest that the ageing process corresponds to a crystallization phenomenon. Given the size of the needles (1 μm long) and the expected Fe...Fe distance (ca 3.5 to 3.8 Å), the crystals are made of ca. 3000 Fe atoms. This very high value may result from the association of smaller crystals. Indeed, the existence of a reversible and hysteretic SCO process relies on strong interactions between coordination polymer chains that can be achieved within such crystals. In contrast, such interactions may be more limited in the amorphous phase. In this context, it is

Fig. 5 (a) SEM and (b) cryo-TEM images of a 9 day-old Fe/ATrz/SO₄ suspension. The amorphous matrix is highlighted in the dotted area, and the crystalline needles by the arrows.

worth pointing out that the investigation of the samples using Small Angle X-ray Scattering (SAXS) showed no characteristic signature, suggesting the absence of periodic organization at the nanometer scale and above.

Preparation and properties of NP-SiSO₃@Fe/ATrz/SO₄ composite gels

Achieving a composite gel structure by addition of particles is a major challenge in self-assembling systems, as sufficient interactions should exist between the two components to achieve percolation while avoiding colloidal destabilization and/or phase separation. This was all the more delicate for the system described here as SCO properties are known to be very sensitive to chemical conditions. In this context, it has been previously shown that stable Nafion-[Fe(HTrz)₃]²⁺ composites exhibiting spin conversion properties could be obtained thanks to the functionalization of the matrix with sulfonate moieties that interact with the inorganic polymer.³⁷ We have thus focused our work on sulfonate-functionalized silica particles (NP-SiSO₃) that could act as counter-ions of the Fe/ATrz chains. The synthesis summarized in Fig. 1c consists in adding NP-SiSO₃ (200 nm in diameter) to EG/H₂O (9/1) solution of FeSO₄·7H₂O, before ligand addition, to induce the formation of a homogeneous gel. This choice proved to be adequate, as gelation occurred after 20 hours when enough particles (140 mg mL⁻¹ NP-SiSO₃, corresponding to a Fe:SO₃ molar ratio of 20:1) were added to the system (Fig. S3, ESI†). The observed gel, denoted as NP-SiSO₃@Fe/ATrz/SO₄, initially white turned pink after 1 day. In contrast, the use of thiol-bearing nanoparticles led to a precipitation of the [Fe(ATrz)₃]SO₄ compound. Interestingly, the addition of bare silica nanoparticles resulted in the formation of a dark precipitate, that probably corresponds to iron oxide particles originating from the oxidation of Fe(II) after coming into contact with the silanol groups at the surface of the particles. This indicates that although the particle surface is not fully covered with sulfonate groups upon functionalization (given that a 200 nm diameter NP-SiSO₃ presents ca. 10⁵ sulfonate groups at its surface compared to ca. 5 × 10⁵ silanol groups for bare particles, see the ESI†),^{49,50} it is sufficient to protect growing iron chains against oxidation.

Rheological studies have been conducted at room temperature to study the mechanical properties and confirmed the gel nature of the composite obtained with NP-SiSO₃ (140 mg mL⁻¹, corresponding to Fe:SO₃ molar ratio of 20:1) and aged for 9 days (Fig. 6a). The average storage modulus G' ranged between 5 and 8 kPa as a function of frequency, whereas the loss modulus G'' was one order of magnitude lower. Noticeably, in the high frequency domain, both G' and G'' tended to decrease, a behavior that was already observed for colloidal suspensions of anisotropic particles.⁵¹ Doubling the particle content to 300 mg mL⁻¹ induced a ca. two-fold increase in G' and G'' values, illustrating the key contribution of NP-SiSO₃ to the mechanical properties of the gel. However, at such high silica concentration, the preparation of a homogeneous composite was difficult due to the immediate gelation so that these conditions were not explored further. The rheological properties

Fig. 6 (a) Rheological profiles under shear stress, at a fixed deformation of 0.1% of the NP-SiSO₃@Fe(ATrz)/SO₄ composites with NP-SiSO₃ concentrations of 140 and 300 mg mL⁻¹ (Fe : SO₃ molar ratio of 20 : 1 and 10 : 1 respectively). (b) Thermal dependence of normalized $\chi_M T$ product of the Fe(ATrz)/SO₄ suspension and NP-SiSO₃@Fe(ATrz)/SO₄ composite gel upon a second cycle (scan rate of 5 K min⁻¹).

of the particle-free suspension could not be measured in this configuration due to its purely liquid behavior.

Compared to the particle-free suspension, XRPD diffractogram of the composite after the same ageing of 9 days showed an enhanced contribution of the broad reflection peak at *ca.* 25°, in agreement with the diffractogram of amorphous silica (Fig. S4, ESI†). However, no significant modification of the crystalline phase (*i.e.* no angular shift or change in the width of the diffraction peaks) of the inorganic polymer network could be evidenced upon particle addition.

Magnetometry measurements have been performed to compare the behavior of the systems with and without particles. Since comparable volumes of the suspension and gel containing the same amount of Fe(II) ions were analyzed, the product $\chi_M T$ (χ_M molar paramagnetic susceptibility) was normalized in order to get the most appropriate comparison. In both cases, a thermal hysteresis was obtained (Fig. 6b). The residual amount of high spin species at low temperature was higher in the absence of NP-SiSO₃ and increased with cycling. In the presence of NP-SiSO₃, a reversible transition was observed. The particles also led to higher upward and downward transition temperatures ($T^\uparrow = 330$ K and $T^\downarrow = 316$ K, respectively) compared to the system without particles ($T^\uparrow = 321$ K and $T^\downarrow = 312$ K, respectively) and a broadening of the hysteresis width ($\Delta T = 9$ K and 14 K for the particle-free suspension and the composite gel,

respectively). Parallely, DSC analysis showed upward and downward transition temperatures of $T^\uparrow_{\max} = 328$ K and $T^\downarrow_{\max} = 315$ K respectively, with a hysteresis width of 13 K (Fig. S5, †). Taking into account the Fe²⁺ concentration per g of sample of *ca.* 8.3×10^{-4} mol g⁻¹, the transition enthalpy for the inorganic component can be estimated to be around 12 kJ mol⁻¹. Note that this value is probably underestimated as there is a possibility that a fraction of the Fe(II) ions is not involved in the transition phenomenon. Yet, the calculated value is in the intermediate range of transition enthalpy for already reported iron(II)-based spin transition systems.^{52,53} Thus it is consistent with a cooperative SCO behavior with a hysteresis width of 13 K. It must be pointed out that the corresponding entropy value is around 40 J mol⁻¹ K⁻¹, indicating a vibrational contribution to the transition. Altogether, these data suggest an enhancement of (i) the ligand field of the iron centers and (ii) the cooperativity between the spin carriers. This supports the existence of significant interactions between the sulfonate groups of the NP-SiSO₃ and the inorganic polymer.

To further investigate the interface between the inorganic polymer and the NP-SiSO₃, 9 day-aged composite gels were observed by TEM and SEM. This evidenced the uniform dispersion of NP-SiSO₃ in the iron-ATrz network. Similar to the suspension, the inorganic network was composed of needles while the amorphous phase was difficult to distinguish due to the presence of the NP-SiSO₃ particles (Fig. 7a and b). Freeze-fracture was then used to allow for the preservation of the hydrated environment of the system before imaging by TEM after replication.⁵⁴ Particle imprints were seen as round craters with irregular marks radiating from them that can be associated with the iron-triazole polymer chains, physically interacting with the silica surface (Fig. 7c and d). Those chains were integrated in the global amorphous polymer network, linking the particles to the system. Some needle-shaped iron-ATrz nanoparticles were also clearly visualized by this technique (white arrows on Fig. 7d). These observations clearly evidence the close interface between the components of the composite system.

Fig. 7 Composite gel NP-SiSO₃@Fe(ATrz)/SO₄ imaged by (a) SEM-FEG, (b) cryo-TEM, (c and d) freeze-fractured TEM. (c) Several imprints of NP-SiSO₃ can be seen (open circles in the picture) with a typical radiating pattern around their perimeter as outlined in the inset. (d) Arrows indicate needle-like structures corresponding to the [Fe(ATrz)₃]SO₄ particles.

As pointed out earlier, XRD and DSC studies on the influence of ageing on the particle-free suspension have suggested that the spin transition properties, related to the existence of high intra- and inter-chains interactions, mainly originate from the crystalline phase. Magnetometry measurements and XRPD studies of the composite have indicated that the addition of the NP-SiSO₃ has a significant impact on the spin transition without modifying the crystallinity of the sample. Parallely, rheology and TEM characterizations have evidenced strong interactions between the particles and the amorphous part of the iron-ATrz matrix. Taken together, these observations support the idea that this amorphous phase itself plays an important role in the spin transition phenomenon. To clarify this point, we prepared solvent-free solid composites. However, as ethylene glycol cannot be evaporated under ambient conditions, it was first exchanged for ethanol in a 9-day matured composite and then air-dried, leading to a pink powder (Fig. 1c). As seen in Fig. 8a, the broad amorphous peaks on the diffractogram decreased in intensity after drying. The remaining peak can be attributed to the presence of silica particles. The well-defined diffraction pattern is identical to that of the initial composite, indicating that the crystalline structure has not been significantly affected by the drying process. The dried powder was then re-exposed to the ethylene glycol/water mixture (1 mL, 9:1 volume ratio). The resulting sample recovered its original gel texture and its diffractogram was similar to that of the starting system, indicating the physical reversibility of the system. Similar observations were made for the particle-free system upon drying and re-solvation (Fig. S6, ESI†).

The magnetic properties and thermal behavior of the dried suspension and composite were also studied (Fig. S7, ESI† for

Fig. 8 (a) XRPD diffractograms of the initial, dried and resolvated NP-SiSO₃@Fe/ATrz/SO₄ composites. (b) Thermal dependence of normalized $\chi_M T$ product (performed at a scan rate of 5 K min⁻¹) of the dried suspension and composite.

DSC data). Fig. 8b shows the magnetic properties of the two dried systems exhibiting similar hysteretic behavior except for a more abrupt HS/LS transition upon cooling in the presence of NP-SiSO₃. In addition, the upward and downward transitions are shifted to higher temperatures compared to their solvated states ($T^\uparrow = 343$ K and $T^\downarrow = 329$ K, see Table S1, ESI†), indicative of a modification of the environment of the Fe(II) centers. Interestingly, the width of the hysteresis is similar for the two powders and close to that of the solvated composite (*i.e.* 14 K). This indicates that in dried systems the presence of particles has a limited impact on the SCO properties.

It is therefore possible to describe these systems in the following manner (Fig. 9). (a) In the suspension, needle-shaped crystals are surrounded by an amorphous solvated network of Fe/ATrz chains. The spin transition properties mainly originate from these crystals. (b) Upon adding NP-SiSO₃, the formation of a gel evidences the percolation of the crystals/matrix assembly. (c) Upon desolvation of the suspension, it can be suggested that the amorphous phase undergoes a shrinking process, increasing the local density in Fe/ATrz chains and embedding the crystals. The high degree of similarity between the diffractograms of the initial and the resolvated systems, in the absence or presence of NP-SiSO₃, led us to hypothesize that the crystallinity of the inorganic network was identical in all systems. This suggests that the different widths of hysteresis between the suspension, the composite and the dried systems should arise from a subtle change in the interactions between the crystals due to some modifications in their environments. In particular, depending on the rigidity of the host, long-range elastic interactions can be mediated or dampened, leading to an increase or decrease of the cooperativity in the system. This has been shown to result in strong modification of the SCO properties of entrapped microcrystalline objects⁵⁵ and conservation of wide hysteresis in dispersed nanoparticles.⁵⁶ Other parameters, such as distance between objects or the strength of their interactions with the matrix should also play a role in the modification of their behavior. In our system, the percolation of the amorphous phase or its desolvation seems to increase the cooperativity between iron-ATrz crystals to a similar extent, leading to a widening of the hysteresis from 9 K in the sol state to 14 K. Thus the mediation of the interactions through percolated solvated

Fig. 9 Schematic representation of (a) the particle-free suspension, (b) composite gel and (c) dry particle-free systems.

amorphous chains is as efficient as in the retracted amorphous phase. However, the drying process has an additional effect as it shifts the transition to higher temperatures, that may be attributed to a positive pressure effect of the network densification on the nanocrystals.^{57–60} This effect could also explain the higher transition temperature of the composite compared to the particle free system.

Conclusions

We report a unique and highly efficient way to obtain spin-crossover materials by combining metallogel and composite approaches. The final material shows an unusual structure consisting of a semi-crystalline coordination polymer system with an amorphous phase that is reticulated by sulfonated silica particles to obtain a gel. This material exhibits a fully reversible and cooperative SCO behavior with upward and downward transition temperatures of 330 K and 316 K, respectively. The study of its structural and SCO features sheds light on the important role played by each of the constituents in its transition properties. This emphasizes the sensitivity of the spin transition phenomenon to multiple factors and the necessity to fully characterize and control the system at different scales. Beyond the system investigated here, this nanocomposite approach is very promising for the elaboration of new functional materials fully integrating the specific properties of coordination polymers.

Experimental

Silica nanoparticles functionalized by sulfonate groups (NP-SiSO₃)

Silica nanoparticles were synthesized following the Stöber process.^{61,62} Sulfonate functionalization of the surface proceeded through a modified procedure consisting of two steps.⁵⁰ Stöber particles were first functionalized with thiol groups by silylation with 3-mercaptopropyltrimethoxysilane (MPTMOS 95%, Aldrich). Typically, 4.12 g of silica particles were redispersed in a mixture of 410 mL ethanol and 9 mL ammonium hydroxide solution before the addition of 4 mL MPTMOS (5 mmol g⁻¹ silica). The mixture was stirred for 40 min at room temperature (RT). Subsequently, the reaction mixture was heated to 80 °C and the total volume was reduced to approximately two-thirds by distillation of ethanol and ammonia at ambient pressure. The mixture was left to cool to RT and was subsequently washed three times with ethanol (by centrifugation at 12 000 rpm for 15 min). Finally, oxidation of thiol groups leads to sulfonic acid functionalized particles. In a typical reaction, 3.6 g of thiol-modified particles were suspended in 150 mL sulfuric acid (H₂SO₄ 30% (w/w) in H₂O, Sigma Aldrich) and stirred for 2 hours at RT. Washing with ethanol and water by centrifugation was used to recover SO₃-modified particles before drying under vacuum. Zeta potential and size distribution measurements were carried out using a Malvern Zetasizer Nano ZS90 instrument giving a strongly negative zeta potential of *ca.* -53 mV in 0.5 M acetic acid (pH 2.5) and a hydrodynamic diameter of *ca.* 200 nm.

The evaluation of the sulfonate density available at the surface of each particle was performed by the titration of thiol grafted prior to their oxidization through the Ellman reaction, taking into account a silica density of 2 g cm⁻³.⁴⁹ The sulfonate density could be evaluated to be 3.5 mol mg⁻¹, *i.e.* about 10⁵ groups per particle.

Particle-free system (Fe/ATrz/SO₄ suspension)

27.8 mg of iron sulfate heptahydrate (FeSO₄·7H₂O, 0.1 mmol) (Sigma-Aldrich, 99%) were dissolved under heating at 50 °C for 30 minutes in 0.75 mL of an ethylene glycol : water mixture (9 : 1 volume ratio) containing 20 mg of ascorbic acid. Parallely, 50.4 mg (0.6 mmol) of 4-amino-1,2,4 triazole (ATrz, C₂H₄N₄, Alfa-Aesar, 99%) was separately dissolved in 0.25 mL of the same ethylene glycol : water mixture at room temperature. After completion of the dissolution of the iron salt, the ATrz solution was placed in an ice bath and the FeSO₄ solution was added dropwise under stirring. This led to a stable suspension that was left to age at 4 °C.

Composite system (NP-SiSO₃@Fe/ATrz/SO₄)

The procedure was analogous to the particle-free systems except that 140 mg of NP-SiSO₃ were suspended in 0.75 mL of the ethylene glycol : water mixture under sonication for 45 minutes before the iron salt was added. Immediately after the mixing process, a colloid suspension was obtained which turned to a gel after about 20 hours of ageing at 4 °C as confirmed by the inverse tube test.

Drying of the suspension and composite systems

Samples were redispersed in 10 mL of ethanol to induce the formation of a precipitate. The mixture was centrifuged, washed 3 times with 10 mL of ethanol and the precipitate recovered before drying under ambient air.

UV-spectroscopy

UV-visible spectra were recorded on freshly prepared mixtures placed in a quartz cuvette with 1 mm optical path length using a Carry 5000 UV-Vis-NIR spectrophotometer. The heating and cooling ramps and the acquisition parameters were chosen to ensure a mean scan speed of 5 K min⁻¹.

Differential scanning calorimetry

DSC measurements were performed on a TA instrument model Q20. Aluminum capsules were loaded with 20–50 mg of the sample and sealed. The set-up and enthalpies were calibrated for temperature using an indium reference (430 K, 3.3 J mol⁻¹). Cooling and heating sweeps were performed at a scanning rate of 5 K min⁻¹ in a N₂(g) atmosphere. The transition temperatures were derived by considering the maximum (*T*_{max}) of the thermal anomalies.

X-ray powder diffraction

XRPD measurements were carried out using Cu Kα1 radiation either on a Philips PW 1830 diffractometer at room temperature or on a Panalytical Xpert pro MPD diffractometer for temperature-dependent experiments. In the latter case, the samples were

deposited on a Si monocrystal in order to have a flat background and then placed in an Anton Paar HTK 1200N oven. The heating and cooling ramps and the acquisition parameters were chosen to ensure a mean scan speed of approximately 1 K min^{-1} .

Rheological measurements

Rheological measurements were conducted on an MCR 302 Anton-Paar rheometer. The geometry used was a 25 mm diameter disk with a rough surface (reference PP 25/S). Freshly prepared samples were placed in PTFE circular chambers with an inner diameter slightly larger than the geometry allowing rheological measurements in the low modulus range. The rheological behavior of the samples was investigated under sinusoidal deformations with a frequency of oscillations ranging from 0.1 to 100 Hz at the set strain (0.1%) and under a normal force of 0.04 N. All experiments and their corresponding measurements were conducted in triplicate.

Magnetic measurements

Magnetic measurements were carried out using a MPMS-5 Quantum Design SQUID (Superconducting Quantum Interference Device) magnetometer operating with an external magnetic field of 0.5 T within the 260–355 K temperature range. Freshly prepared samples (about 200 mg of the Fe-ATrz suspension or 170 mg of the NP-SiSO₃@Fe-ATrz composite) were introduced into an EPR tube. The tube was then sealed, and after 9 days the tube was fixed to a cane and placed in the magnetometer at 298 K. Cooling and heating sweeps were performed at a scanning rate of 5 K min^{-1} . Paramagnetic susceptibility data (χ_{para}) were obtained subtracting from the experimental susceptibility data, the diamagnetic contributions (sample, RPE tube). These latter contributions were estimated from the slope of the χT curve at high temperature (344–356 K) over which no spin state change takes place. The magnetic susceptibility vs. temperature curves were then normalized to allow the comparison of the thermic loop between all samples.

Electron microscopy

Scanning electron microscopy (SEM) imaging was performed using a Variable Pressure Hitachi S-3400N after depositing a thin layer of the sample on aluminum pads without any further metallization.

All the Transmission Electron Microscopy (TEM) observations were conducted on a FEI Technai Spirit G2 operating at 120 kV equipped with a Gatan cryo-holder operating at -180°C . Images were recorded on a Gatan Orius CCD camera.

For cryo-TEM, a drop of sample was deposited on plasma treated QUANTIFOIL grids before vitrification: the excess sample was removed by blotting with filter paper (Whatman #4) to obtain a thin film before plunging the grid into liquid ethane cooled by liquid nitrogen.

For freeze-fracture experiments, samples placed between two copper holders were rapidly frozen by plunging them into liquid nitrogen. They were kept frozen and transferred into a freeze-fracture apparatus developed by Dr J.-C. Homo (IGBMC, Strasbourg). The samples were cryo-cleaved and platinum was

evaporated onto the sample at a 45° angle, and then carbon at a 90° angle with respect to the surface. The samples were warmed up to room temperature and the replicas were rinsed by acidic treatment and deposited on 400 mesh grids.

Conflicts of interest

There are no conflicts to declare.

Acknowledgements

The authors would like to thank L. Frenck, J. Camperi and E. Coquin for the screening of polar solvents to obtain metallo-gels, B. Baptiste and L. Delbes for the temperature-dependent XRPD measurements performed on the IMPMC XRD platform and E. Rivière for the magnetic measurements performed on the ICMO Technical Platform.
