Keywords: Lithium-ion batteries; α -MnO₂; Green tea; Black tea; Polyphenols; Cathode materials.

ABSTRACT

For more than a century, manganese dioxides (MDOs) have been used as electrochemically active materials in energy storage and conversion applications. To reduce the cost and hazardous impact of synthesis, a redox method was used to prepare MnO₂ using extracts of green (GT-MnO₂) and black (BT-MnO₂) tea as biological reducing agents. Polyphenols present in the extracts of tea not only reduce Mn⁷⁺ ions but also act as "capping agents" to stabilize and prevent the produced MnO₂ nanoparticles from degradation and aggregation. Elemental, structural properties and morphology of nanosized α -K_xMnO₂ were studied by thermogravimetric analysis, X-ray powder diffraction and Raman spectroscopy, which revealed the different crystallinity between GT-MnO₂ and BT-MnO₂ due to the strength of the antioxidant species. Electrochemical investigations highlight the beneficial presence of K⁺ ions in (2×2) tunnels; with a higher concentration, α -K_{0.135}MnO₂ exhibits a discharge specific capacity of 155 mAh g⁻¹ after 20 cycles at C/26 rate.

1. Introduction

Great interests have been directed towards developing new energy storage and conversion systems to overcome the expected lack of fossil fuels and to alleviate the environmental problems [1, 2]. The rechargeable lithium-ion battery is one of the most important and effective batteries for supplying energy [3,4]. Therefore, great efforts have been made to develop new electrode materials for the next generation of lithium-ion batteries having high energy and power density and excellent cycling performance to satisfy market demands [3,5,6].

Low cost, high theoretical capacity, environmental friendliness, and natural abundance are the main advantages of manganese dioxides, MnO_2 (MDOs), which make them promising electrode materials for lithium-ion batteries and supercapacitors [7,8]. However, the practical application of MnO₂ as electrode material for lithium-ion batteries is actually limited by the poor conductivity, large volume expansion and aggregation during Li insertion/extraction, which limits its rechargeability. Brousse et al. [9] reported electronic and ionic conductivities of 0.009 and 0.01 S cm⁻¹, respectively, for cryptomelane compared to $\sim 6 \times 10^{-6}$ and 0.015 S cm⁻¹, respectively, for birnessite. That is why composite materials of MnO₂ have been fabricated with various conducting materials (see [10] for a review). In particular, MnO₂@TiO₂ composite used as an anode recently delivered a capacity of 802 mAh g⁻¹ at the current rate of 200 mA g⁻¹ after 200 cycles, and still retained 400 mA h g⁻¹ at a higher current rate of 1 A g⁻¹ [11]. Three-dimensional ZnFe₂O₄@MnO₂ hierarchical core/shell nanosheet arrays as battery-type electrode exhibit high capacity of 1084 C g⁻¹ at current density of 2 A g⁻¹ with coulombic efficiency of 96.1% after 5000 cycles [12]. Recent MnO₂-based composites including MnO₂/carbon, MnO₂/graphene, MnO₂ nanowires@Ni_{1-x}Co_xO_y heterostructures, CoMoO₄@C@MnO₂ core-shell structures and MnO₂/carbonized cotton textile hybrids have been developed as electrodes in supercapacitors [13-17].

Different MDO polymorphs such as α -, β -, γ - and δ -MnO₂ phases with various morphologies including nanorods, nanowires, nanosheets and nanobelts have been investigated to get better electrochemical performance [18–20]. To control the crystallite size, degree of crystallinity, the morphology, and specific surface area, the preparation method should be chosen carefully. A recent example is provided by the synthesis of nanosheet-based MnO₂

hollow capsules, which delivered a capacity of 1182.9 mAh g⁻¹ for the initial cycle and 198.4 mAh g⁻¹ after 500 cycles [21]. Numerous methods to synthesize MnO₂ include sol-gel [22], hydrothermal methods [23-25], refluxing method [26] and wet-chemical methods [27-31]. For most of them, strong mixing, long time and high temperature are required, resulting in the waste of a lot of energy [32,33]. It is then desirable to develop facile, cheap, environmentally benign, and size control routes to prepare MnO₂ nanoparticles [34]. In particular, biogenic approaches for the preparation of nanomaterials can be a good alternative to achieve the advantages mentioned above [35]. Non-hazardous chemicals, biodegradable polymers, available fruits, vegetables, herbs containing high concentration of polyphenols can act as antioxidants or reducing agents and can also provide a protective coating. Saving energy owing to the availability and facile synthesis at room temperature and ambient atmosphere is the main advantage of using environmentally benign plant extracts as an antioxidant for the synthesis of nanoparticles [36,37].

In a recent review on nanostructured MnO₂ as electrode material for energy storage, we pointed out that the problems of the Zn/MnO₂ battery (limited cycling life and power) have now been entirely solved. The alkaline Zn/MnO₂ batteries now outperform the Li-ion batteries not only by the lower price, but also by their performance, both in energy and in power density [10]. In particular, Liu et al. reported such a battery, the capacity of which was 285 mAh·g⁻¹ (MnO₂), with capacity retention of 92% over 5000 cycles [38]. MnO₂ is thus a promising candidate to be the electrode of next generation of commercial rechargeable batteries. The next problem is thus to optimize the synthesis of this material in terms of cost and environmental friendliness. The present work addresses this problem by employing a facile, eco-friendly and cost-effective method using green and black teas to prepare α -MnO₂.

Black and green teas exhibiting different structures contain number of flavonoids (one of constituents of polyphenols) that can be used as species to prepare MnO₂ from the redox reaction of KMnO₄. They have excellent antioxidant properties due to the high phenolic content [39]. Green tea leaves are not fermented and hence, do not go through the oxidation process that black tea undergoes, making it extremely rich in simple flavonoids called epigallactocatechin gallate (the EGCG), a popular antioxidant. The oxidation process used to obtain black tea converts catechins to more complex varieties called theaflavins and thearubigins. Hence, green tea is ahead of black tea in its antioxidant quality and quantity. Fig.

1 summarizes the chemical structures of the major flavonoids found in both green and black tea. The oxidation process modifies only the type of flavonoids present without changing the level and antioxidant activity of these flavonoids [40-43].

The goal of this paper is to synthesize MnO₂ nanoparticles by a simple redox synthesis method using extracts of green and black tea as reducing agents for their use as highperforming electrode materials in energy storage systems. We pay a special attention to characterize the crystal chemistry of α -type MnO₂ prepared from redox reaction of potassium permanganate, which always contains a residual fraction of K^+ ions in the 2×2 tunnels preserving the structural stability of this material. Note that most of numerous works published in the literature neglect this aspect; only few papers consider the presence of potassium in the cryptomelane framework [44-51]. Two samples were prepared using a redox synthesis procedure assisted by biologic anti-oxidant reagents that are extracts of tea. Structural and morphological properties of MDOs are investigated by X-ray diffraction (XRD), thermal gravimetric analysis (TGA), specific surface area, pore volume and mean pore size, Raman scattering (RS) spectroscopy, scanning electron microscopy (SEM), and transmission electronic microscopy (TEM). Further electrochemical tests are also performed by cyclic voltammetry (CV), galvanostatic experiments and electrochemical impedance spectroscopy (EIS). Our results reveal that nanostructured α -MnO₂ particles exhibit both improved specific capacity and high rate capability Note only intrinsic properties of α -MnO₂ are considered here, so that the results are not comparable with the electrochemical properties of the composites above mentioned, since the other elements of the composites are introduced just because they improve the performance.

2. Experimental

2.1. Sample preparation

Two samples of MnO_2 were prepared using a green synthesis method via redox reaction between KMnO₄ and extracts of green tea (GT-MnO₂) and black tea (BT-MnO₂). A commercial green tea bag of 1.8 g was boiled in 100 mL distilled water for 5 min to extract the green tea solution. The cooled prepared extract was added drop by drop to 3 g KMnO₄ acidified with 2 mL of 2.5 mol L⁻¹ H₂SO₄ in 100 mL of distilled water. After stirring vigorously for 1 h at room temperature, the color of the solution changed from purple to black due to the complete reduction of KMnO₄ by the extract of green tea. The black precipitate was isolated by filtration and washed several times with distilled water to remove most of the expected K⁺ from the precipitate. The collected precipitate was dried overnight at 90 °C, then calcined at 300 °C for 5 h in ambient atmosphere. The same procedure was used to prepare BT-MnO₂ sample using the extracts of boiled two bags (2 g) of black tea added to 3 g of KMnO₄.

2.2. Structural and electrochemical characterization

Thermal gravimetric (TG) measurements were carried out using an analyzer (Perkin Elmer, TGA 7 series) in the temperature range of 50–1000 °C in air at a heating rate of 10 °C min⁻¹. The crystal structure was investigated by X-ray powder diffraction using a STOE STADI-P with Mo-K_{α 1} radiation (λ =0.70932 Å), curved Ge111 monochromator and Si-strip detector from Dectris. Samples were placed in 0.5-mm glass capillaries. Specific surface area, pore volume and mean pore size of the samples were obtained by performing N₂ physisorption experiments at 77 K on Micromeritics ASAP (Tristar 2020, USA) analyzer using Brunauer-Emmett-Teller (BET) and Barrett-Joyner-Halenda (BJH) multipoint methods. The micropore volume (V_{pore}) was calculated from the amount of N₂ adsorbed at a relative pressure (P_r = P/P_0) of 0.1 and 0.95, respectively. Raman scattering (RS) spectra were collected on a LabRam Evolution HR (HORIBA) spectrometer equipped with a Nd:YAG laser (523 nm, 1 mW). The final spectrum consists of two independent acquisitions with a total acquisition time of 720 seconds. The morphology and size of particles were investigated by scanning electron microscopy (SEM) (model Quanta FEG 250) and transmission electron microscopy (TEM) (model JEM-2100, JEOL, Japan). Swagelok type cells were used to characterize the materials electrochemically. For this purpose, the active material was mixed with carbon back (Super P, Timcal) in the ratio 8:2. The cathode loading was 4.2 mg cm² (geometric surface area 1.8 cm^2). Two layers of Whatman GF/B separators and 1 mol L⁻¹ LiPF₆ in an ethylene carbonate and dimethyl carbonate solution (1:1) mixture were used for the cell assembly. Lithium metal was used as counter electrode. The material was characterized galvanostatically using the LICCY cycling station (Lithium Cell Cycler Liccy, KIT). VMP3 potentiostat (Biologic Science Instruments, France) was used to record the cyclic voltammograms (CV). Electrochemical impedance spectroscopy (EIS) was carried using a phase sensitive multimeter (model PSM 1700, UK) in the frequency range 0.01 Hz–100 kHz using a voltage bias of 5 mV.

3. Results and discussion

3.1. Elemental and structural studies

The cryptomelane (α -MnO₂) phase commonly prepared via redox reaction of KMnO₄ or $K_2Mn_2O_8$ contains potassium as an essential constituent filling the 2×2 tunnels. Potassium ions are incorporated during the synthesis because of the excess of K^+ ions in the solution. α -MnO₂ crystallizes in the body-centered tetragonal structure with I4/m space group; the unit cell contains 16 oxygen sites, 8 sixfold coordinated ^{VI}Mn sites, and 2 eightfold coordinated tunnel sites (^{VIII}K). Consequently, the formula of the α -phase is K_xMn₈O₁₆, in which the concentration of K⁺ ions is variable, but K never occupies more than 50% on any of the sites in the lattice [38]. This concentration can be determined from thermogravimetry (TG) by analyzing the weight loss of chemisorbed water in the tunnels and the decomposition temperature from MnO₂ to Mn₂O₃ (Fig. 2). Poyraz et al. [46] reported that the K_xMn₈O₁₆ samples with low K⁺ content, K_{0.32}Mn₈O₁₆, have a lower decomposition temperature of 510 °C compared to T=580 °C for the samples with high K^+ content ($K_{0.75}Mn_8O_{16}$). Fig. 2a shows the differential (DTG) weight loss for GT-MnO₂ and BT-MnO₂ synthesized by redox reaction between KMnO₄ and extracts of green tea and black tea, respectively. The decomposition of α-K_xMnO₂ to Mn₂O₃ operates via an exothermic reaction that takes place at temperatures 500<7<650 °C. Distinct weight losses caused by the reduction of tetravalent Mn⁴⁺ ions to trivalent Mn³⁺ ions correspond to oxygen evolution $2MnO_2 \rightarrow Mn_2O_3 + \frac{1}{2}O_2$ that is completed at T~650 °C [49]. Using previous DTG analyses, an almost linear relationship (R=0.984) between the temperature of the MnO₂ to Mn₂O₃ phase transition and the concentration of K⁺ ions in the 2×2 tunnels (Fig. 2b) was established. Data summarized in Table 1 show that the BT-MnO₂ has a lower concentration of K⁺ ions (only about half the value) than GT-MnO₂.Fig. 3 shows the XRD patterns for GT-MnO₂ and BT-MnO₂ samples. All the reflections can be indexed with the α-MnO₂ structure (JCPDS 44-0141). The X-ray diagram of GT-MnO₂ has the feature of nanostructured material with broadening of Bragg reflections (curve a), while curve (b) shows that BT-MnO₂ is an amorphous or highly disordered material. Scherrer crystallite sizes of

 8.0 ± 0.2 nm for the GT-MnO₂ sample and 4.4 ± 0.2 nm for the BT-MnO₂ sample were calculated from the half-width of the <211> reflection at $2\theta=37.6^{\circ}$ (with Scherrer parameter K=0.88). A Rietveld refinement for GT-MnO₂ using the program package Fullprof [52] confirms nanosized needles along the *c*-axis. Refinement parameters are $R_p=16.7$; $R_{wp}=18.6$; $R_{exp}=14.05$; $\chi^2=1.75$ and Bragg R-factor=5.8. As suggested by Vicat et al. [45] the structure is described with an interstitial potassium site on Wyckoff position 4e(0,0,z) in addition to the 8hsites for Mn, O1, O2, with z~0.3. The occupancy of this site is approximately 0.068/0.25 =27%; the other sites are fully occupied and the z-coordinate converges at 0.35. This leads to a potassium content of 0.135 per formula unit, consistent with the value of 0.11(2) from the TG measurements. The formula of K_{0.135}MnO₂ leads to an average oxidation state +3.865 for Mn ions, in which the number of ^{VI}Mn³⁺ is equal to the number of ^{VIII}K⁺. Lattice parameters listed in Table 2 are in good agreement with reported values [53]. Besides the scale and background points, the refined parameters were isotropic atomic displacement parameter (ADP), lattice parameter, atomic positions and two parameters for anisotropic size broadening. Note that the ratio K:Mn = 0.135 is very close to the value for cryptomelane structure $K_{0.125}MnO_2$ (KMn₈O₁₆) with half occupancy of the 4e tunnel sites.

Note that very fast preparation of the GT-MnO₂ sample, did not allow a complete removal of K^+ ions, despite several washings with distilled water. Consequently, a higher number of alkali ions was trapped in comparison with BT-MnO₂, which was formed slowly. The synthesis process is affected by the strength of the reducing agent, which governs the ionic extraction from the 2×2 cavities and controls the diffusion of K^+ ions. As an experimental result, the redox reaction assisted by black tea is not as fast as with green tea, because of the difference in the flavonoid structure and the strength of the antioxidant species.

Fig. 4 presents the SEM and TEM images of $GT-MnO_2$ and $BT-MnO_2$. Submicron-sized particles with average size ~400 nm have almost identical shape and distribution for both samples. These secondary particles are composed of interconnected nanoneedles with diameter of 5 nm and length of ~100 nm as shown in the TEM pictures. Note that the shape and size of both the agglomerates and the nanoneedles of GT- and $BT-MnO_2$ are similar.

The pore characteristics, i.e. BET surface area, pore volume and mean pore size, are shown in Table 3. The value S_{BET} of 49.8 m² g⁻¹ for GT-MnO₂ can be compared with 9.37 m² g⁻¹ for

 α -MnO₂ synthesized via hydrothermal treatment of a precursor γ -MnO₂ [54] and S_{BET}=41 m² g⁻¹ for γ -MnO₂ synthesized by Pechini technique [55].

Raman scattering (RS) spectra of GT-MnO₂ and BT-MnO₂ nanoneedles are displayed in Fig. 5. As Raman spectroscopy is a powerful tool for the analysis of the structure at the molecular scale, this technique was used to study the crystallinity of the manganese dioxide depending on the synthesis procedure, i.e. the nature of the reducing agents. The RS spectrum of GT-MnO₂ exhibits well-resolved bands at 181, 380, 510, 577, 630 and 754 cm⁻¹, while the Raman bands of BT-MnO₂ are broadened and poorly resolved, which is the fingerprint of a highly disordered material. Note that the Raman features of our polycrystalline samples do not allow the observation of all active modes $(6A_g+6B_g+3E_g)$ predicted by the group factor analysis of the body-centered tetragonal structure [56]. The two high-frequency bands at 577 and 630 cm⁻¹ (Ag modes), which originate from breathing Mn-O vibrations perpendicular to the direction of double chains of edge-shared [MnO₆] octahedra, are the typical fingerprints of the tetragonal 2×2 tunnel structure. The low-frequency Raman band at 181 cm⁻¹ assigned to an external vibration comes from translational motion of the [MnO₆], while the band at 380 cm⁻¹ is attributed to the O-Mn-O bending vibrations. The shoulder at 754 cm⁻¹ is related to the antisymmetric Mn-O stretching vibrations. These outlined Raman features are in good agreement with results reported in the literature for α -MnO₂ [57,58]. Note that the degree of crystallinity of synthesized MnO₂ samples has a strong impact on the intensity of the v_{577} and v₆₃₀ bands. In summary, Raman data match well with results from XRD showing that GT-MnO₂ has a better crystallinity than BT-MnO₂.

3.2. Electrochemical behavior

Electrochemical properties and discharge performance of MnO₂ nanoparticles synthesized by the green synthesis assisted by extracts of tea were investigated by cyclic voltammetry, galvanostatic charge-discharge experiments, and cycling tests at different current densities from 10 to 400 mA g⁻¹ (1C=260 mA g⁻¹). Fig. 6 shows the first 20 cyclic voltammograms carried out at scan rate of 0.1 mV s⁻¹ in the potential range 1.5-3.5 V vs. Li⁺/Li⁰. The first discharge-charge process is unique with features dominated by the broad cathodic peaks $V_{c,1}$ at 2.45 and 2.40 V for GT-MnO₂ and BT-MnO₂ electrodes, respectively, and the corresponding oxidation peaks observed at 3.10 and 2.40 V. The broadness is attributed to the poor crystallinity rather than the morphology of nanoneedles. Such behavior has been reported several times [48,59-61]. It was conjectured that local activation can take place in the material during the initial lithium insertion. Dai et al. [59] believed that the change of the initial chargedischarge curves is due to ion-exchanged reaction. Zhang et al. [61] studied the chemical states of the species in K_xMnO₂ using X-ray photoelectron spectroscopy (XPS) and concluded that potassium is extracted from the host lattice, which described the CV profile evolution during the first cycle. The electrochemical reactions of the second cycle show different profiles with two pronounced sets of redox peaks. Values of the redox potentials are listed in Table 4. Note that the difference between V_{red} and V_{oxid} is $\Delta V = -0.15$ V irrespective of the degree of structural order. The subsequent cycles have almost the same profile, so that the lithium insertion/extraction process occurs most probably with the same mechanism. In the forthcoming cycles these CV data show a good rechargeability for both samples, so that a good structural stabilization is obtained after the second cycle. The initial broad cathodic peak seems to be dependent on the K⁺ content in α -K_xMnO₂; the higher the K⁺ content the higher the cathodic potential [49,59-61]. This is consistent with the assumption that Li⁺ motion requires a stable tunnel framework, which is ensured by the presence of larger cations such as K^+ . It is well known that Li^+ ions are located on off-center 8h and 8h' Wyckoff positions (near the walls of the 2×2 tunnels) and the presence of K^+ ions on the centered 4e sites affects the electrochemical features and the overall discharge capacity [45].

Fig. 7 illustrates the available sites of the cryptomelane structure occupied by Li⁺ and K⁺ cations. The initial electrochemical modification is attributable to the lithium-cell formation, plus the structural evolution that results from the so-called "loss of lithium inventory" [62]. This loss is due to the trapping of a small amount of Li⁺ ions inserted during the first discharge and remaining in the tunnel structure, which results in stabilization of the tetragonal phase. This behavior is consistent with the two pseudo-plateaus observed in the discharge profiles (see Fig. 8). Similar results have been observed previously [63,64]. Johnson et al. [63] reported the immediate appearance of two sets of redox peaks in α -MnO₂ prepared by the reaction between Mn₂O₃ and H₂SO₄. The evolution of the cyclic voltammogram was observed in the initial lithiation for very small nanocrystallites, i.e. *L*<10 nm [64]. In the present study, the morphology of nanoneedles of 5 nm diameter favors the insertion of Li⁺ ions on the two

different 8*h* and 8*h*' Wyckoff sites of the $Li_xK_{0.135}MnO_2$ structure; the first set of redox peaks correspond to the lithiation of 8*h* position at low Li concentration, while the second set is due to the 8*h*' site occupation for high Li content that requires different energies of formation [65]. To the contrary, Zhang et al. [61] reported a strong cathodic peak at ~2.2 V during the first cycle, which shifted toward higher potential for the second and further cycles, showing that lithium insertion-extraction in/from cryptomelane-type K_{0.25}Mn₂O₄ occurred as a single set of redox reaction at 2.5/3.0 V because the sample in their work consisted of microspheres composed of nanofibers in the range of 10-20 nm diameter.

Fig. 8 shows the discharge-charge profiles of $MnO_2//Li$ cells recorded at constant current density 10 mA g⁻¹ (C/26) in the potential range 1.5–3.5 V vs. Li⁺/Li⁰ including GT-MnO₂ and BT-MnO₂ as positive electrode materials. In the entire discharge range, the discharge cell potential decreases slowly and evidences the presence of two pseudo-plateaus; each of them appears as an "S-shaped" curve, which indicates a topotactic reaction for the lithium insertion in both electrodes. However, the voltage decay is more pronounced in BT-MnO₂, which is characteristic of a disordered electrode material [1]. These features are thus consistent with the structural analysis.

The net effect of the presence of K⁺ ions in 2×2 tunnels (located on 4*e* Wyckoff positions) is observed in the discharge curves. The initial specific capacity of highly disordered BT-MnO₂ is ~236 mAh g⁻¹, while the well crystallized GT-MnO₂ delivers ~198 mAh g⁻¹. The lower initial capacity is attributed to the presence of the higher concentration of electrochemically inactive K⁺ ions trapped on 4*e* sites inside the large tunnel (4.6 Å). In GT-MnO₂, more than half of the 4*e* sites are occupied by potassium, against only one quarter in BT-MnO₂. This inactive cation may hinder the Li insertion into the tunnel and impede the diffusion during the discharge process [25]. The structural stabilization of K⁺ cation is clearly evidenced in the GT-MnO₂ structure, for which the capacity fading is lower than for BT-MnO₂ (Fig. 9). Note that a similar capacity loss for Li// α -MnO₂ is consistent with the mean oxidation state +3.865 for Mn ions determined form the Rietveld refinement. Except for the two first cycles, the coulombic efficiency on the third and subsequent cycles for GT-MnO₂ shows good rechargeability with efficiency close to 99% even at constant current density of 200 mA g⁻¹ (≈0.75C).

The cycling performance, i.e. discharge capacity and coulombic efficiency over 54 cycles, of cells with K_xMnO₂ as cathodes is shown in Fig. 9. The GT-MnO₂ sample shows the best results for capacity retention. The relevant coulombic efficiency of the K_{0.135}MnO₂ electrode remains around 100% after several cycles, indicating the good reversibility. At C/26 rate, the specific discharge capacity of GT-K_xMnO₂ decreases slowly from 161 mAh g⁻¹ (3rd cycle) to 141 mAh g⁻¹ (54th cycle). The capacity loss rate is 0.25% and 0.58% per cycle for GT-K_xMnO₂ and BT-K_xMnO₂, respectively. Both samples suffer from an irreversible capacity in the first cycle, but it is a limited loss of ~30 mAh g⁻¹ for GT-MnO₂ so that GT-MnO₂ retains 73% from its initial capacity at the 20th cycle, whereas BT-MnO₂ retains only 62%. The first cycle irreversible capacity (1st IC) is an intrinsic weakness of MDOs. Several examples are obtained in the literature. The 1st IC of 85 mAh g⁻¹ was reported for birnessite MnO₂ nanobelts [66], Huang et al. [67] indicated a 1st IC of 75 mAh g⁻¹ for macroporous β -MnO₂ and Cheng et al. [66] reported a 1st IC larger than 40 mAh g⁻¹ for α -MnO₂ nanowires. Covering α -MnO₂ nanorods by a thin layer of carbon improves the long-term capacity retention, but does not inhibit the initial capacity loss that confirms the trapping of a fraction of lithium ions into the internal cavities during the cell formation [27]. Yang et al. [69] showed that hydrothermally synthesized α -MnO₂ composed of nanorods ~20 nm diameter delivers specific capacity of 189 mAh g⁻¹ at a discharge current 50 mA g⁻¹.

Rate performance was tested for both samples at various current densities in the range 10-400 mA g⁻¹ (1C=260 mA g⁻¹). Figs. 10a and 10b show the rate capabilities and the modified Peukert plot, respectively. As for many electrodes, the decay of the discharge capacity follows a semi-logarithmic law with increase of the current passed through the cell. After the tests at higher C-rates up to 1.5C, the capacity delivered at the initial current density of 10 mA g⁻¹ was recovered, which gives evidence of the electrochemical reversibility and structural stability of the samples. A reversible capacity of 32 mAh g⁻¹ was delivered for the Li//GT-MnO₂ cell cycled at 1.5C, while that of the Li//BT-MnO₂ vanished due to the sluggish kinetics of Li⁺ ions associated with the structure.

Fig. 11 shows the electrochemical impedance spectra (EIS) of MnO₂ electrodes over the frequency range 0.01 Hz-100 kHz as a function of the cell potential: 3.0 V and 1.8 V vs. Li^+/Li^0 corresponding to the lithium insertion $x\approx 0.05$ and ≈ 0.6 in Li_xMnO_2 , respectively. All EIS features are composed in the high-frequency region of a semi-circle that reveals the

electrolyte resistance R_s and the charge transfer resistance R_{ct} and inclined lines in the lowfrequency range attributed to the Warburg impedance σ_w and the electrode capacitance. The Warburg regime observed at low frequencies gives evidence that the insertion mechanism of Li⁺ ions into the MnO₂ electrode is strongly controlled by a diffusion process. In this regime, the impedance varies with the angular frequency ω according to the law [70]:

$$Z' = R_{\rm s} + R_{\rm ct} + \sigma_{\rm w} \,\omega^{-1/2},\tag{1}$$

The Warburg impedance σ_w is obtained from the slope of Z° vs. $\omega^{-1/2}$ in the low-frequency range (Fig. 11). Typical values of σ_w are listed in Table 5. EIS can be used to evaluate the apparent Li-ion diffusion coefficient $D_{\text{Li}+}$ from the low-frequency Warburg impedance according the relation [71]:

$$D_{Li^+} = \frac{1}{2} \left[\frac{RT}{F^2 A C_{Li} \sigma_W} \right]^2, \tag{2}$$

where *R*, *T* and *F* are the usual constants, *A* the surface area of the electrode-electrolyte interface, C_{Li} is the lithium-ion concentration in the electrode. Note that estimation of *A* is rather difficult. Instead of the apparent geometric surface area of the electrode (1.8 cm²), we have used the S_{BET} values that take into account the porosity of the electrodes. Randles parameters and diffusion coefficient $D_{\text{Li}+}$ are reported in Table 5.

3.3. Discussion

The cryptomelane α -MnO₂ tunnel-based structure include well-aligned 2×2 (4.6×4.6 Å²) tunnels occupied with large K⁺ cations and empty 1×1 (1.9×1.9 Å²) tunnels intergrowth along the *c* axis. α -MnO₂ is believed to show topotactic reduction of Mn (Li⁺ solid solution) during lithiation [48]. The role of large cations (K⁺) occupying the central 2*a* site of 2×2 tunnels is considered as follows. The presence of large tunnel counter cations in the MnO₂ lattice is a necessary condition for the growth of the hollandite-type MnO₂ (HMDO) structure and prevents the formation of other MnO₂ polymorphs [53]. Generally, the presence of K⁺ ions in the (2×2) tunnels of the hollandite lattice has an impeding effect for the chemical diffusion of

the Li⁺ ions. This is due to the much bigger ionic radius of K⁺ (r_i =1.33 Å) than Li⁺ (r_i =0.69 Å), which prevents the facile lithium motion in the MnO_2 framework [72]. The stabilizing K⁺ ions only partially occupy the space inside structural tunnels of cryptomelane K_xMn₈O₁₆, leaving enough volume for Li⁺ ion insertion, leading to superior discharge rate performance compared to the ones of pristine α -MnO₂ material. Byles et al. [73] evaluated the electronic and ionic conductivities of tunnel structured MnO₂ and shown the stabilization of K⁺ and Mg²⁺ cations in cryptomelane and todorokite frameworks. Our EIS data show that the charge transfer resistance is a function of the K⁺ content: R_{ct} =83.2 Ω for K_{0.135}MnO₂ increases to 105.8 Ω for K_{0.06}MnO₂. The role of tunnel cation on electrochemical performance of cryptomelane type α -MnO₂ (K_xMn₈O₁₆) cathode materials with tunable K⁺ content has been investigated by Poyraz et al. [46]. The electrochemistry of the K_xMn₈O₁₆ electrode with varying K/Mn ratios (0.000 to 0.094) was evaluated. For x=0.32, the α -MnO₂ electrode showed higher voltage, higher specific energies, and improved capacity retention compared to the material with x=0.75. Another effect of the interstitial K⁺ cation incorporation in the α -MnO₂ lattice is the formation of newly occupied electronic states that appear inside the original MnO₂ bandgap, indicating mixed Mn^{4+} and Mn^{3+} in K_xMnO₂ [74]. This indicates that the presence of K⁺ inside the 2×2 tunnels can enhance the electronic conductivity of α -MnO₂ through electron hopping between heterovalent Mn pairs (Mn^{4+}/Mn^{3+}). It was found from EIS data that the presence of K⁺ inside the 2×2 tunnels of α -MnO₂ nanoneedles improves both their electronic conductivity and Li⁺ diffusivity. These enhancements facilitate favorable electrode kinetics, and thus result in good rate performance of Li/α -MnO₂ based batteries.

Compared with other nanoscale-sized lithiated MnO₂ cathodes reported previously, the present α -MnO₂ powders exhibit similar trends in kinetics [49,75-79]. The lithium diffusion coefficient 3.4×10⁻¹⁴ m² s⁻¹ at 20 °C in electrolytic Li_{1.0}MnO₂ (battery grade γ -phase) was early determined by galvanostatic technique [75]. Using cyclic voltammetry, Bach et al. [76] estimated a diffusion coefficient of Li⁺ ions of $\approx 10^{-10}$ cm² s⁻¹ in the hydrated a-phase K_{0.062}MnO₂. Current step method was used to measure the Li chemical diffusion coefficient of $D_{\text{Li}}=4\times10^{-11}$ cm² s⁻¹ in Li_{0.4}MnO₂ [75]. D_{Li^+} values were found to vary in the range from 1×10^{-10} cm² s⁻¹ for the fully charge (delithiated) state to 2×10^{-11} cm² s⁻¹ for the fully discharged (lithiated) state [78,79]. Yuan et al. [49] show that after K⁺ removal the charge transfer

resistance (R_{ct}) increases and the diffusion coefficient D_{Li^+} decreases from 1.91×10^{-12} cm² s⁻¹ in K_{0.25}MnO₂ to 7.16×10^{-13} cm² s⁻¹ in K_(0.25-x)MnO₂. Our results are consistent with those of previous reports. We show that kinetics for Li⁺ ions is a function of the concentration of K⁺ cations into the tunnels; diffusion coefficient D_{Li} in K_{0.06}MnO₂ is lower than that in K_{0.135}MnO₂, which is consistent with $D_{Li}=1.9 \times 10^{-12}$ cm² s⁻¹ for K_{0.25}MnO₂ reported by Yuan et al. [49]. From electrochemical impedance spectroscopy (EIS), we have shown the effect of K⁺ on the ionic transport of lithium inserted into the α -K_xMnO₂ lattice and on the electronic conduction.

4. Conclusions

A green synthesis route involving the redox reaction between KMnO₄ and antioxidant reagent was used to obtain nanosized α -MnO₂. Cheap and benign biological reducing reagents were obtained from extracts of green tea and black tea. In both cases, the samples were obtained in the form of particles with ~400 nm in size, composed of interconnected needles with diameter of 5 nm and length of ~100 nm. Further characterization by thermal gravimetric analysis and Raman scattering emphasized different structural properties for the two samples, related to the different antioxidant reagents in the green and black tea. These samples synthesized by using biological reducing agents showed electrochemical performance comparable with that of samples prepared by conventional more expensive methods using chemical reducing agents. The sample synthesized using black tea showed better initial capacity (~231 mAh g⁻¹) than the sample synthesized using green tea GT-MnO₂ (~214 mAh g⁻¹). However, GT-MnO₂ shows better capacity retention (73% after 20 cycles at current density 10 mA g⁻¹) than BT-MnO₂ (62% at the same cycle number). GT-MnO₂ also showed improved rate capabilities compared to BT-MnO₂. This cheaper and scalable redox synthesis process is thus a significant improvement with respect to the industrial processes currently used to fabricate the commercialized MnO₂ batteries. The chemical diffusion coefficient of Li⁺ ions inserted in Li_xMnO₂ frameworks was determined from EIS experiments as a function of the discharge state that show higher kinetics for Li⁺ transport in K_{0.06}MnO₂ compared with K_{0.135}MnO₂.

Fig. 5. Raman scattering spectra of GT-MnO₂ and BT-MnO₂ α -phase recorded using a 523 nm laser excitation.

Fig. 6. Cyclic voltammograms carried out at scan rate of 0.1 mV s⁻¹ in the potential range 1.5-3.5 V vs. Li^+/Li^0 .

Fig. 7. Crystal structure of α -MnO₂ showing insertion sites at Wyckoff position 4*e*, 8*h* and 2*b*. The 8*h* (*x*,*y*,0) and 2*b* (0,0,½) sites are coplanar by adding the centering (½,½,½) planes perpendicular to the *c*-axis, while the 4*e* site is located at a general position (0,0,*z*). Small (red) spheres are oxygen, large (green) spheres are Mn cations inside the MnO₆ octahedra, and yellow spheres are potassium cations.

Fig. 8. Discharge-charge profiles of $MnO_2//Li$ cells including (a) BT-MnO₂ and (b) GT-MnO₂ as positive electrode materials recorded at current density 10 mA g⁻¹ (C/26) in the potential range 1.5–3.5 V vs. Li⁺/Li⁰.

Fig. 9. Cycling performance cycled at constant current density 20 mA g^{-1} (\approx C/10) in the potential range 1.5-3.5 V vs. Li⁺/Li⁰ and coulombic efficiency of GT-MnO₂ and BT-MnO₂.

Fig. 10. (a) Rate capability at various current densities from 10 to 400 mA g^{-1} (1C=260 mA g^{-1}) and (b) Modified Peukert plots for GT-MnO₂ and BT-MnO₂ electrodes.

Fig. 11. EIS spectra of GT-MnO₂ and BT-MnO₂ electrodes as a function of the cell potential E=3.0 V ($x\approx 0.05$) and E=1.8 V ($x\approx 0.6$).

Table 1. Potassium content filling the 2×2 tunnel of K_xMnO₂ estimated from TG analysis.

	Decomposition	
Sample	temperature (°C)	K^+ content
GT-MnO ₂	593±2	0.11(2)
BT-MnO ₂	530±2	0.06(2)

Table 2. Lattice parameters of the $K_{0.135}$ MnO₂ sample (space group *I*4/*m*) prepared with lemon juice and lemon peel as reducing agents. Rietveld refinements were performed by the FULLPROF program.

Parameter	P-MnO ₂	
<i>a</i> (Å)	9.826(7)	
<i>b</i> (Å)	9.826(7)	
<i>c</i> (Å)	2.845(2)	
$V(Å^3)$ Crystallite size (nm) R_{wp} χ^2	274.1 (3)	
	2.5(5)	
	18.6	
	1.75	

Table 3. The surface and pore characteristics of MnO_2 powders.

Compound	$S_{\rm BET}$ (m ² g ⁻¹)	Pore volume (cm ² g ⁻¹)	Mean pore size (nm)
GT-MnO ₂	49.8	0.066	11.5
BT-MnO ₂	33.2	0.054	7.7

	Cathodic potential at	Redox potentials at 2 nd and		
Material	1 st cycle	subsequent cycles		
	(V)	Reduction	Oxidation	
BT-MnO ₂	2.40	2.31	2.44	
		2.61	2.76	
GT-MnO ₂	2.45	2.30	2.44	
		2.65	2.80	

Table 4. Redox potentials recorded by cyclic voltammetry for GT-MnO₂ and BT-MnO₂ α -phases.

Table 5. Randles parameters and diffusion coefficient D_{Li^+} of GT- and BT-MnO₂ electrodes.

Electrode	Cell voltage(V)	$R_{\mathrm{s}}\left(\Omega\right)$	$R_{\mathrm{ct}}\left(\Omega\right)$	$\sigma_{w}\left(\Omega\;s^{\text{-}1/2}\right)$	$D_{Li^+} (cm^2 s^{-1})$
GT-MnO ₂	3.0	14.5	83.2	40.2	5.2×10 ⁻¹¹
	1.8	14.3	60.2	45.9	4.0×10 ⁻¹¹
BT-MnO ₂	3.0	16.5	105.8	63.1	2.1×10 ⁻¹¹
	1.8	16.0	67.9	74.0	1.5×10 ⁻¹¹
