A B S T R A C T

This study presents new field and petrological data on carbonated metasomatic rocks from the lawsonite-eclogite units of Alpine Corsica. These rocks form along major, slab-scale lithological boundaries of the subducted Alpine Tethys plate. Our results indicate that a large variety of rocks ranging from metamafic/ultramafic to metafelsic can react with carbon-bearing fluids, leading to carbon sequestration at high-pressure conditions. The process of carbonation includes both replacement of silicates by high-pressure carbonate, and carbonate veining. The field, microstructural and mineralogical data strongly suggest that the metasomatism was mediated by the infiltration of external fluids of mixed origin, including both mafic/ultramafic and metasedimentary sources. Our results support the following three-step evolution: (i) Release of aqueous fluids by lawsonite and/or antigorite breakdown at depth; (ii) Fluid channelization along the base of the metasedimentary pile of the subducted lithospheric plate and related reactive fluid flow leading to carbonate mineral dissolution; (iii) Further interactions of the resulting carbon-bearing fluids with slab-forming rocks at depths of ca. 70 km and carbonation of pre-existing silicate-rich lithologies. This study highlights the importance of carbonate-bearing fluids evolving along down-T, down-P paths, such as along slab-parallel lithological boundaries, for the sequestration of carbon in subduction zones, and suggests that similar processes may also operate in collisional settings.

1. Introduction

Subduction zones control an important part of the carbon cycle by regulating the exchanges between shallow and deep carbon reservoirs (e.g., Hammouda, 2003; Hayes and Waldbauer, 2006; Dasgupta and Hirschmann, 2010; Dasgupta, 2013; Evans, 2012; Poli, 2015). The amount of carbon that enters subduction zones is currently estimated to range from 40 to 66 Mt C/yr (Kelemen and Manning, 2015). This carbon is dominantly hosted in carbonate minerals present in both sediments and altered oceanic crust and mantle rocks (Plank and Langmuir, 1998; Alt and Teagle, 1999; Jarrard, 2003; Plank, 2014).

The study of the petrological evolution of subducting carbonate-bearing rocks is therefore crucial for the understanding of the global carbon cycle (Kerrick and Connolly, 1998, 2001; Molina and Poli, 2000; Gorman et al., 2006). Subducted carbonate may experience different mechanisms of recycling, which are in most cases enhanced by open-system conditions and infiltration of external fluids. These mechanisms include processes related to the reactivity between carbonates and silicates (e.g. decarbonation reactions; Kerrick and Connolly, 1998, 2001;

Gorman et al., 2006), processes related to carbonate solubility in aqueous fluids (e.g. carbonate dissolution; Frezzotti et al., 2011; Ague and Nicolescu, 2014), processes of carbonate reduction (to either solid or fluid reduced phases; Malvoisin et al., 2011; Galvez et al., 2013; Vitale Brovarone et al., 2017), and melting (Schneider and Eggler, 1986; Hammouda, 2003; Poli, 2015). Several works have focused on the mechanism that can release carbon from subducting slabs and transfer it to shallower reservoirs, most notably the mantle wedge and volcanic arcs above subduction zones. Decarbonation reactions releasing CO₂ are expected to be particularly efficient at forearc conditions (Kerrick and Connolly, 1998, 2001; Gorman et al., 2006), whereas carbonate dissolution has been identified as a major process for carbon release occurring at forearc and possibly subarc depths (Frezzotti et al., 2011; Ague and Nicolescu, 2014). Accounting for the ensemble of these processes, Kelemen and Manning (2015) estimate deep carbon fluxes from the subducting slab into the shallow mantle of 4 to 60 Mt C/yr. Accordingly, the authors suggest that potentially most subducted carbon (40 to 66 Mt C/yr) is released from the slab into deep fluids.

Conversely, much less is known regarding the reactivity of carbon-bearing fluids, generated by decarbonation/dissolution processes, with silicate rocks in the subducting slab. Equivalent processes are known at low-pressure conditions in both oceanic and on-land settings, where they can sequester significant amounts of carbon, including

atmospheric CO₂ (e.g. [Kelemen and Matter, 2008](#)). In HP metamorphic settings, recent studies on the exhumed eclogite-facies units of Alpine Corsica and the Western Alps report that, during flow, carbon-bearing fluids can be extremely reactive with mafic and ultramafic rocks and lead to high-pressure (HP) rock carbonation ([Piccoli et al., 2016](#); [Scambelluri et al., 2016](#)). HP rock carbonation is a newly discovered process of carbon sequestration that can contribute to counterbalance carbon fluxes due to mobilization processes (both decarbonation and dissolution), with potential large-scale implications for the global carbon cycle ([Piccoli et al., 2016](#)). The identification of HP carbonation in exhumed metamorphic terranes, however, may be challenging owing to the absence of diagnostic mineral assemblages and the effect of deformation and late metamorphic overprinting.

In this contribution, we present a detailed field and petrological dataset for several occurrences of carbonated metasomatic rocks in the lawsonite eclogite-facies terrains of Alpine Corsica (France). The

aim of this work is threefold. Firstly to provide an exhaustive picture of the nature and diversity of these carbonated metasomatic products and their protolith rocks. Secondly, elucidate general petrological and geochemical features characterizing carbonate metasomatic processes at HP conditions in subduction zones. Lastly, discuss the fluid composition and sources. A conceptual model of large-scale reactive fluid flow is then proposed based on the field, petrological, and geochemical observations in order to better assess the impact of this process on the carbon inventory in subduction zone reservoirs.

2. Geological setting

2.1. Geology of Alpine Corsica and the San Petrone unit

Alpine Corsica occupies the northeastern part of the island of Corsica (France) and is a segment of the Alpine orogenic system ([Jolivet](#)

Reconstructed tectonostratigraphy of unaltered rocks

Tectonostratigraphy of metasomatic rocks

et al., 1991; Molli and Malavieille, 2011; Fig. 1a). The belt is subdivided into three domains (see Vitale Brovarone et al., 2013 for review): 1) the continent-derived units; 2) the Schistes Lustrés complex; and 3) the uppermost thrust sheets (*Nappes Supérieures*) (Fig. 1b). Altogether, these units were thrust over the western and southern part of the island, which largely escaped the Alpine subduction and orogenesis. The Schistes Lustrés complex consists of remnants of subducted Mesozoic slow-spreading oceanic and passive margin lithosphere of the Tethys Ocean, and shows lithostratigraphic features analogous to those of the eclogite-facies units exposed in the Piemonte Zone of the Western Alps (e.g. Queyras/Combin/Monviso/Rocciavré/Zermatt–Saas area; Lagabrielle and Lemoine, 1997; Lombardo et al., 2002; Vitale Brovarone et al., 2014a). The Schistes Lustrés complex forms a N-S antiformal stack with metamorphic grade increasing from the top to the bottom, with the exception of the lowermost structural unit (Castagniccia unit, Fig. 1c). The peak metamorphic grade varies from subgreenschist-facies conditions of about 300 °C and 0.4 GPa to lawsonite blueschist- and lawsonite eclogite-facies conditions of 500–550 °C and ~2.3 GPa (e.g. Fournier et al., 1991; Ravna et al., 2010; Vitale Brovarone et al., 2013).

In this study, we focus on the San Petrone unit, which belongs to the lawsonite eclogite-facies terrains (Vitale Brovarone et al., 2011a) (Fig. 2a). The San Petrone unit is interpreted to represent a coherent segment of subducted Jurassic hyper-extended passive margin or ocean-continent transitional lithosphere (Vitale Brovarone et al., 2011a; Beltrando et al., 2014). The unit consists of a basal body of serpentized mantle peridotites overlain by a laterally variable lithostratigraphy comprising: i) slivers of continental basement rocks; ii) pillow metabasalts; and iii) Mesozoic metasedimentary rocks (Fig. 2b). By analogy with present-day passive margins, the basal serpentized peridotites are interpreted as sub-continental mantle rocks exhumed and altered on the seafloor during Jurassic (hyper)extension (Manatschal, 2004; Beltrando et al., 2014 and references therein; Picazo et al., 2016). Evidence of these events is also well documented in the San Petrone unit, such as scattered bodies of ophicarbonates found along the top of the serpentinite testifying for mantle alteration along a paleo-seafloor (Vitale Brovarone et al., 2011a). Metagabbros are rare in this unit and are found as small pods within the serpentinite. The continental basement slivers lie directly upon the serpentinite (Fig. 2a,b,c-d), and contain both orthogneiss and carbonate-free paragneiss. These continental basement slivers are interpreted as continental extensional allochthons emplaced on top of the exhumed mantle substratum during the hyper-extension of the continental margin (Vitale Brovarone et al., 2011a; Beltrando et al., 2014). Metabasalts form large bodies (Fig. 2a) with structural position equivalent to the continental slivers, and never underlie or overlie them. Mesozoic metasedimentary rocks variably overlie the serpentinite ($\pm$ ophicarbonate), the continental slivers, and/or the metabasalts (Fig. 2a,b). The base of the Mesozoic metasedimentary suite comprises the original basal unconformity of marine sediments in the Tethys basin (Vitale Brovarone et al., 2011a; Beltrando et al., 2014) and, therefore, was a major lithological boundary during the Alpine subduction. The Mesozoic metasediments can be divided into early post-rift and post-rift metasediments (Fig. 2b). The first group consists of metacherts (likely radiolarian metacherts) and marbles of inferred Jurassic sedimentary age; the second group mainly includes calcschists *sensu stricto*, i.e., pelitic layers alternating with carbonate-rich layers of Cretaceous sedimentary age (Vitale Brovarone et al., 2011a). This composite tectonostratigraphic sequence is folded by a series of large (km in length) N-S non-cylindrical anticlines and synclines that locally overturn the overall upright tectonostratigraphy (Fig. 2b). Because of the non-cylindrical folds, the entire lithostratigraphy is affected by local and discontinuous synformal and antiformal structures with N-S trending fold axes (Fig. 2b,c,d). The whole tectonolithostratigraphic suite of the San Petrone unit underwent

consistent peak metamorphic conditions of about 500–550 °C and ~2.2–2.4 GPa (Vitale Brovarone et al., 2011b) in the Late Eocene (U-Pb zircon ~34 Ma, Martin et al., 2011; Lu-Hf garnet, Vitale Brovarone and Herwartz, 2013).

2.2. Fluid-rock interaction and metasomatism in the San Petrone unit

Previous studies have documented rocks affected by strong fluid-rock interactions and metasomatism localized along the contact separating the serpentized mantle rocks and the overlying lithologies (Vitale Brovarone et al., 2011a, 2014b; Martin et al., 2011; Piccoli et al., 2016) (Fig. 2b–e). Two successive metasomatic stages were identified: (i) A first event characterized by fluid-mediated lawsonite-diopside crystallization (Stage#1 metasomatic rocks) and constrained to prograde-to-peak metamorphic conditions (2–2.2 GPa; 500–550 °C) by petrological and geochemical data and U-Pb zircon geochronology (Martin et al., 2011; Vitale Brovarone et al., 2014b and references therein); (ii) A second event characterized by carbonate metasomatism and formation of carbonate-rich rocks (Stage#2 metasomatic rocks; Piccoli et al., 2016). The second event occurred through the interplay of fluid-silicate interactions, hereafter termed silicate carbonation, and veining. Mineral assemblages, including coexisting carbonate + omphacite + garnet, and stable isotope geothermometry (493 ± 30 °C) coupled with previous P-T-paths (Vitale Brovarone et al., 2011b) constrain this second event to near peak metamorphic conditions (Piccoli et al., 2016). Of particular interest for this study are Stage#2 carbonated metasomatic rocks, for which we report herein new field and petrological data.

3. Tectonostratigraphic occurrence of carbonated metasomatic rocks

Carbonated metasomatic rocks in the San Petrone unit occur along three main types of regional lithological interfaces (Fig. 2), which are described in the following together with their most notable structural and lithological features. The reconstruction of the pre-metasomatism metasedimentary sequences was done by integrating field and petrological observations from our survey and previous studies. Fig. 3 summarizes the main field lithostratigraphic observations by means of interpretative tectonostratigraphic logs and representative field images.

3.1. Serpentinite-Mesozoic metasediments

This regional lithological interface crops out several times over about 13 km (Fig. 2a). The best examples of metasomatism along this type of lithological interface are exposed in the localities of Col del Prato, Punta Favalta and Loriani (Figs. 2a,c; 3a and 4a,b,c). In these zones, the serpentinite below the contact is massive to foliated. Only the very top centimeters of the serpentinite exhibit a marked schistosity parallel to the contact with the overlying rocks; these schistose zones are also more weathered than unfoliated serpentinite. At the regional scale, relicts of the Mesozoic metasedimentary rocks overlying the serpentinite and unaffected by metasomatism commonly consist of quartz-rich, carbonate-free layers alternating with impure marbles (Fig. 3a1,a2), followed upward by calcschists *sensu stricto* (pelitic layers with more or less abundant carbonate layers). The quartz-rich layers, commonly metacherts (Fig. 3a2), are continuous and range in thickness from a few cm to about 1 m, and are frequently observed at the base of the metasedimentary sequence (first 3 m above the contact). Metacherts commonly contain Mn-rich minerals suggesting transformations of Mn-bearing radiolarian metacherts typical of the lowermost portion of the Tethyan Mesozoic sedimentary cover sequences preserved in this unit (Vitale Brovarone et al., 2011a and references therein). The metasedimentary rocks are affected by polyphase deformation leading

Fig. 4. Outcrop of carbonated metasomatic rocks along different lithological contacts. **a)** Loriani outcrop. Here the metasomatic rind width ranges between 1 m and 2.5 m. **b)** Detail of Loriani outcrop showing the heterogeneous carbonation of the silicate rock. **c)** Shear zone in the metasomatized contact in Punta Favaltà area. The dashed red lines indicate the carbonated metasomatic rock level, the detail of which is reported in the white box. **d)** Metasomatic rind on the orthogneiss in contact with serpentinite nearby Punta Caldane. **e)** Aja Rossa outcrop and simplified geological cross section (modified after Vitale Brovarone et al., 2014b). **f)** Outcrop in Punta Caldane area: mafic block embedded in carbonate matrix. A detail of a carbonate crack-seal opening within the mafic block is reported in the white box. (For interpretation of the references to colour in this figure legend, the reader is referred to the web version of this article.)

to non-cylindrical and disharmonic folding and a marked composite schistosity (Fig. 3a1) that locally resulted in boudinage of the quartz-rich layers.

The contact between the serpentinite and the metasediments is commonly affected by a strongly asymmetric metasomatic front formed at the

expense of the lower part of the metasedimentary pile overlying the serpentinite (first 1–3 m), and with no marked evidence for metasomatism in the serpentinite (Figs. 3a3,a4, 4b; Martin et al., 2011; Vitale Brovarone et al., 2014b; Piccoli et al., 2016). The metasomatic halo consists of both diopside-lawsonite-rich rocks (Stage#1 metasomatism)

and carbonated metasomatic rocks (Stage#2 metasomatism). Field observations attest to the relative chronology of the two metasomatic events, with Stage#2 carbonation partially replacing Stage#1 metasomatic rocks. These two metasomatic end-members (diopside-lawsonite and carbonated metasomatic rocks) are observed at various scales with two main modes of occurrence. In some cases the two rock types form a layered structure that mimics (Fig. 3a2, a4) the structure of pristine metasedimentary sequences composed of folded impure marbles and metachert layers (Fig. 3a1, a3). Some outcrops show partial replacement of the protolith metasedimentary rocks by the metasomatic assemblages. The most remarkable example was observed in the Loriani outcrop (Figs. 2a, 4a), where a progressive transformation of a former metachert layer into diopside-lawsonite-rich rocks can be clearly seen on the outcrop (Fig. 3a4). The diopside-lawsonite domains are then replaced by carbonate. This process leads to heterogeneous consumption and segmentation of the silicate-rich layers of the initial metasedimentary sequence (Fig. 4b). The latter process is commonly mediated through processes of fracturing and brecciation of the Stage#1 rocks and formation of carbonate crack-seals, along with chemical replacement of silicates by carbonate (Piccoli et al., 2016). Field and microstructural observations indicate that both metasomatic events post-dated the main regional-scale folding event.

In the Punta Favalta area, a ~8 m thick sequence of variably metasomatized and intensely deformed rocks is found atop the regional serpentinite. Here, the serpentinite basement is intensely folded and capped by ophicarbonates. A small lens of metasediments is sandwiched in a tight, recumbent syncline. The outcrop is located in the overturned limb of the fold (Fig. 2d). The rocks overlying the serpentinite are intensely metasomatized and affected by strong deformation along a main shear zone. Fig. 4c shows the shear zone between less deformed lawsonite-rich rocks and highly strained carbonated metasomatic rocks.

3.2. Serpentinite-continental basement rocks

Metasomatism also affected initially carbonate-free, pre-Alpine continental basement rocks resting on top of the serpentinite (Figs. 2b, 3b, c). The extent of metasomatism most commonly inversely correlates with the thickness of the continental basement slivers. The most notable examples of metasomatism in this structural setting are found in the area between Punta di Caldane, Monte Muffraje and Aja Rossa (Fig. 2a, d, e). In the southern part of the study area (Punta di Caldane; Fig. 2e), a 15–20 m thick (minimum thickness) sliver of continental basement rock crops out discontinuously and forms patches of variable thickness. In the vicinity of Punta di Caldane, this body mainly consists of orthogneiss ($\pm$ discontinuous paragneiss lenses; Figs. 2e, 3c2, 4d) overlying the serpentinite. The uppermost tens of cm of the serpentinite nearby the contact show a marked schistosity parallel to the contact and no alteration halos have been observed. Above the contact, the first 2 m of rock consist of Stage#1 diopside-lawsonite metasomatic rock formed at the expense of the orthogneiss, as indicated by the primary structure of the orthogneiss preserved in the metasomatic halo. In the lowermost part of the metasomatic rind, several carbonate veins cut across the metasomatized orthogneiss (Fig. 3c4). The veins reach about 2 cm in thickness and have sharp contacts, with no alteration selvage observable in the field. No evidence for carbonation by replacement of former silicates was observed here.

The same contact is exposed in the Monte Muffraje area. Here, a 2 to 3 m-thick patch of metasomatic rocks cap the serpentinite, and are followed upwards by unaltered Mesozoic calcschists. The contact between the metasomatic rind and the serpentinite is parallel to the regional schistosity and dips gently to the west. As for the previous cases, the serpentinite does not show marked evidence for strong fluid-rock interactions. In the field, the distinction between metasomatized pre-Alpine and Mesozoic rocks cannot be easily made owing to the outcrop conditions and the pervasive metasomatism. The metasomatic rind consists of both Stage#1 and Stage#2 metasomatic rocks. Stage#1 rocks

dominantly consist of diopside and lawsonite, and occur as dismembered, partially corroded patches embedded in a Stage#2 carbonate-rich matrix (Fig. 3b4). Stage#1 domains preserve a weak foliation inherited from the protolith. In the Stage#2 rocks, carbonate in most cases forms rods oriented at high-angles to the regional schistosity. Carbonate and carbonate + lawsonite veins, often with crack-seal texture, are widespread and locally discordant to the regional foliation (Fig. 3b4). The orientation of the foliation in the patches of Stage#1 rocks is consistent at the outcrop scale (i.e. no clast rotation) and indicates that carbonate precipitation occurred statically.

As in the previous case, in the Aja Rossa area, a thin (a few meters) slice of continental basement rocks is extremely metasomatized (Fig. 4e). The metasomatic rind in this outcrop extends over the continental material and also affects the overlying Mesozoic metasediments for a total thickness of ca. 8 m (Martin et al., 2011; Vitale Brovarone et al., 2014b).

3.3. Continental crust-Mesozoic metasediments

Metasomatic rocks and HP carbonation were also observed along the top of the pre-Alpine continental basement rocks in contact with Mesozoic metasedimentary rocks. The two most notable examples crop out in the area of Punta di Caldane and to the East of Punta Ventosa (Fig. 2a, e). In the vicinity of Punta di Caldane, Mesozoic metasedimentary rocks cap a 15–20 m thick sliver of continental basement rocks, which in turn overlie the basal serpentinite (Section 3.2). In the first 5 m above the contact with the orthogneiss, a chaotic ensemble made of deformed clasts/blocks of mafic/ultramafic rocks dominated by green amphibole + chlorite ($\pm$ lawsonite, $\pm$ ankerite), dispersed in a carbonate-rich matrix (Figs. 3c1; 4f) (hereafter, carbonated mafic/ultramafic rocks) is found. Some clasts are intensely strained and form discontinuous layers, with dimensions ranging from a few cm to ca. 50 cm in diameter. Ca-carbonate crack-seals associated within green amphibole-chlorite lenses are also observed (Fig. 4f). Furthermore, hydraulic breccias composed of blocks of metasomatic origin (diopside + lawsonite) sealed by rod-shaped carbonate are locally observed within the first few meters of the sequence. Quartz-rich rocks overlie the chaotic sequence of carbonated mafic/ultramafic rocks. No unaltered protolith rocks with comparable structural features were found, with the exception of a small body of brecciated and carbonated serpentinites (ophicarbonates) about ~150 m from the Punta Ventosa outcrop. The metasedimentary sequence becomes more homogeneous and dominated by calcschists from ~5 m above the contact with the continental sliver.

In the region of Punta Ventosa (Fig. 2a), carbonated mafic/ultramafic rocks overlying the continental crust are also present. In this locality, impure marble layers with abundant deep green clinopyroxene, blue amphibole, garnet, and minor quartz (Fig. 3c3), overlie the carbonated mafic/ultramafic rocks. This kind of carbonated rock never occurs in the metasedimentary sequence far from major lithological interfaces, where only monotonous rocks such as calcschists are found.

The heterogeneity of the chaotic sequence in these two areas makes the identification of individual metasomatic events and the reconstruction of a pre-metasomatism tectonostratigraphy more challenging than the previous cases.

4. Methods

4.1. Scanning electron microscopy and electron microprobe

Petrographic thin sections were carbon coated for scanning electron microscopy (SEM). Observations were performed at a working distance of 7.5 mm using a Zeiss Ultra 55 field emission gun SEM operated at 15 kV with a 120 μ m aperture. Backscattered electron (BSE) mode was used to investigate chemical heterogeneities using an Angle Selective Backscattered Detector (AsB) or an Energy Selective Backscattered

Table 1

Summary table reporting mineral paragenesis of the study rocks.

Locality	Interface	Protolith	Stage#1	Stage#2	Late stages
<i>Loriani</i>	Serpentinite/ Mesozoic metasediments	Metachert, Calcschists	Di, Lws	Cc, Agt, ($\pm$ Gt)	Pmp, Ep, Ab
<i>Col de Prato</i>	Serpentinite/ Mesozoic metasediments	Metachert, Calcschists	Di, (Lws?)	Cc, Omph, Gt	Ab, Phg
<i>Punta Favalta</i>	Serpentinite/ Mesozoic metasediments	Metachert (?)	Ep, Rieb, Qtz, Hem, Deer	Cc, Agt, Gt, Qtz, Hem, Deer	–

Detector (EsB). Energy dispersive X-ray spectrometry (EDXS) maps were acquired using an EDXS QUANTAX system equipped with a silicon drift detector XFlash 4010 (Bruker). Data were processed with the software Esprit (Bruker). Mineral analyses were performed on a Cameca electron microprobe (either SX-100 or SX Five) (Camparis, Université Paris 6). Common analytical conditions were adopted for spot analyses (15 kV, 10 nA, wavelength-dispersive spectroscopy [WDS] mode), using Fe_2O_3 , MnTiO_3 (Mn, Ti), diopside (Mg, Si), orthoclase (Al, K), anorthite (Ca) and albite (Na) as standards. The automated Cameca ZAF procedure was used for quantification. For clinopyroxene, garnet, and amphibole ferric and ferrous iron contents were calculated on the basis of charge balance, using 6, 12 and 23 oxygens per formula unit, respectively, and with fixed cations per formula unit: 4, 8 and 13, respectively. All iron was assumed to be Fe^{3+} for pumpellyite and epidote, and Fe^{2+} for mica. The water content of hydrous minerals was calculated assuming stoichiometry.

5. Petrography

Here we present an overview of the characteristic microstructures of the main rock types studied, including the protolith rocks and their metasomatic equivalents from the three types of tectonostratigraphic settings described in the previous section. Table 1 summarizes the petrological evolution of the study samples during Stage#1 and Stage#2 metasomatism by reporting the most characteristic mineral paragenesis for the main metasomatic stages. Mineral modal volumes for the studied thin sections are reported in Table S1, mineral chemistry is described in the next section, and representative analyses are reported in Table S2. Carbonates are always compositionally pure CaCO_3 , unless otherwise specified. In the matrix, calcite replaces aragonite, whereas fresh aragonite is locally preserved as inclusions in garnet and hematite.

5.1. Unaltered protolith rocks

5.1.1. Mesozoic metasediments

Relicts of Mesozoic metasediments little or unaffected by metasomatism range from metachert (sample cor16-42d) to quartz-carbonate rich rocks (samples 1cor12-20c and 1cor14-5, Fig. 3a1, a2). In thin section, the first variety displays disjunctive schistosity (Passchier and Trouw, 2005) marked by phengite rich layers and oriented blue amphibole alternating with coarse-grained granoblastic quartz domains (Figs. 5a, 6a). Small euhedral garnets grew in the amphibole-phengite domains (Fig. 6a). The second rock type is characterized by alternating mm-thick layers of carbonate and quartz (Figs. 5b, 6b). Euhedral garnet is found in the silicate-rich domains (Fig. 6b). Iron-rich carbonate and opaque minerals form clumps wrapped by phengite, blue amphibole, and epidote (Fig. 5b). Mn-rich epidote is also locally present (1cor14-5c, Table S1). Calcschists *sensu stricto* (samples cor13-32 and 1cor12-11q) have a marked schistosity defined by phengite flakes embedded in a carbonate + quartz granoblastic matrix. In these samples, accessory phases are chlorite, epidote, opaque minerals, and carbonaceous material,

the latter being concentrated in the phengite-bearing domains. Pseudomorphs after lawsonite may be present and consist mainly of white mica, chlorite, and opaque minerals.

5.1.2. Pre-Alpine gneiss

Pre-Alpine rocks forming the continental basement slices are polymetamorphic micaschists and metamafic paragneiss intruded by Permian granitoids (now orthogneiss, Fig. 3b1,b2,c2) (Vitale Brovarone et al., 2011a and references therein; Martin et al., 2011). The paragneiss may contain inherited HT garnet as a main distinctive feature (Fig. 6g; Martin et al., 2011), whereas the orthogneiss commonly contains jadeite porphyroblasts (Fig. 3c2). The identification of a pre-Alpine protolith in extremely metasomatized rocks was done based on field relationships, such as transitional mineralogical variations statically overprinting pre-Alpine basement rocks, or by the identification of the above diagnostic minerals as relict phases.

5.2. Carbonated metasomatic rocks

5.2.1. Serpentinite-Mesozoic metasediments contacts

Stage#2 carbonated metasomatic rocks (Piccoli et al., 2016) generally display a mm to cm-scale banded structure of alternating carbonate-rich and silicate-rich layers (Figs. 3a3; 5c). Carbonate-rich domain contains Ca-carbonate, together with garnet and green-pleochroic clinopyroxene (Table 1). Silicate-rich domain contains diopside and lawsonite (Table 1), together with a variable amount of garnet, and late stage product like green amphibole, quartz, epidote (with allanitic cores), pumpellyite and phengite (Table 1). Whenever present, phengite and amphibole preferred orientation marks the regional foliation. The boundaries between the two types of compositional layers range from sharp to embayed in response to different degrees of interaction between the carbonates and the silicates (Piccoli et al., 2016). Crystal size ranges from μm to mm. Carbonaceous material is locally found in both compositional domains. Carbonate is found as both calcite and fresh aragonite, the latter preserved as inclusions in garnet (Piccoli et al., 2016). Ca-carbonate most commonly forms pseudo-hexagonal rods oriented at high angle to the main rock fabric. Clinopyroxene is a common phase in both the carbonate-rich and silicate-rich portions of the rock, and is commonly present in multiple generations resulting from the successive stages of metasomatism (Stage#1 and Stage#2, see also next section for compositional features). In samples 1cor12-20d and 1cor14-12b, clinopyroxene crystals form either stubby neoblasts or fibrous aggregates (Fig. 6c), both sub-mm in size, and with pale- to deep-green pleochroism. Fibrous aggregates have embayed rims when in contact with the carbonate matrix. In sample 1cor12-20d, clinopyroxene crystals display a marked optical zoning between core and rim. The core, inherited from Stage#1 metasomatism, is pale green and commonly exhibits extensive corrosion and replacement by Ca-carbonate (Figs. 6c, 7a), whereas the rim—the stable clinopyroxene of Stage#2 metasomatism—is green pleochroic (omphacite) and is in textural equilibrium with the matrix carbonate (Fig. 6c). Garnet has different habits, from euhedral to poikilitic and

Fig. 5. Thin section scans. **a)** Non-metasomatized metachert from Loriani outcrop (sample cor16-42d). Phengite and blue amphibole levels are highlighted with colors. **b)** Quartz-carbonate-rich metasediment from Col del Prato area (sample 1cor12-20c). Minerals are shaded with colors. Carbonate and quartz domains are shaded in yellow and grey respectively. Epidote, blue amphibole, garnet and ankerite are shaded in yellow, blue, red, and brown, respectively. **c)** Banded carbonated metasomatic rock from Col del Prato. The scan shows the occurrence of silicate rich levels composed by omphacite, garnet and carbonate (bands delimited by dashed red lines). Note that large garnet porphyroblasts are present in both carbonate and silicate rich domain (sample 1cor12-20d). **d)** Banded carbonated metasomatic rock from Aja Rossa area. Note that carbonate cracks open in the diopside + lawsonite domain (delimited by the dashed red line). **e)** Banded carbonated metasomatic rock from the shear zone in Punta Favaltà area (sample 1cor14-6a). The dashed red line marks the compositional banding. **f)** Jadeite-bearing carbonated metasomatic rock from Mt. Muffraje area (sample 1cor14-10 g). Jadeite crystals are partially replaced by carbonate and phengite and embedded in a matrix composed by carbonate + quartz + phengite. (For interpretation of the references to colour in this figure legend, the reader is referred to the web version of this article.)

skeletal, and shows strong and variable compositional zonation even by optical microscopy (Fig. 6d,e). Poikilitic garnet contains aragonite/calcite, clinopyroxene, epidote, carbonaceous material, chlorite, and quartz inclusions. In sample 1cor12-20d and cor13-28c, large garnet crystals may have optical zoning with pink core and colorless rim. In other samples, garnet may display sigmoidal or concentric zoning with colorless core and pink rim (Fig. 6d,e). BSE imaging revealed that the garnet compositional zoning can be complex, as shown in Fig. 7e–h. In Fig. 7e–f, poikilitic garnet with quartz and carbonate inclusions clearly shows a compositional zoning that varies as a function of the nature of the included mineralogy: garnet around carbonate inclusions is dark grey and has lower Mn content, whereas garnet around quartz inclusions is light grey because of higher Mn content. Fig. 7g–h show similar zoning in skeletal garnet: when garnet is in contact with Stage#2 clinopyroxene it has lower Mn and higher Ca and Fe. Bright garnet is preserved far from the inclusions (Fig. 7g). *Lawsonite* is found as either large (100–500 µm, Lws1), locally inclusion-rich porphyroclasts (with inclusions of mainly quartz, titanite, rutile and carbonaceous material) or smaller (<50 µm in size), inclusion-free euhedral crystals (Lws2). In some samples, clinopyroxene is not present and the dominant silicate phase is green amphibole. *Pumpellyite* locally replaces Lws1, either rimming or totally replacing the lawsonite porphyroclasts, and is interpreted as a late stage retrograde phase (sample cor13-28c, Table S2). All together, the microstructural relationships suggest that the Stage#1 paragenesis clinopyroxene1 (Cpx1) + lawsonite1 (Lws1) is replaced by the Stage#2 paragenesis composed by carbonate + clinopyroxene2 (Cpx2) ± garnet ± lawsonite2 (Lws2) ± blue amphibole.

Metasomatic rocks from the Punta Favalta outcrop (sample 1cor14-6a) display some remarkable features compared to other samples in the same structural position. The rock is characterized by a banded structure with domains of quartz + blue amphibole + hematite + deerite, and domains of carbonate + clinopyroxene + garnet + hematite + deerite with relicts of blue amphibole and epidote (Fig. 5e). A detailed description of this sample is beyond the aim of this paper, however, key observations about carbonation deserve to be pointed out. In carbonate-rich domains, blue amphibole is only locally found as a relict phase being replaced by clinopyroxene and, locally, epidote is pseudomorphically replaced by garnet or rimmed by clinopyroxene (Fig. 6f). *Ca-carbonate* is in textural equilibrium with clinopyroxene, garnet, but also hematite and deerite (Figs. 6f and S1). Fresh aragonite was found as inclusion in hematite suggesting that carbonation took place at oxidized conditions. *Deerite* is quite abundant and occurs as inclusions in both quartz (together with hematite) and calcite. It is worth noting that the assemblage quartz + deerite + hematite has been widely reported in quartzite and metacherts from many localities of Alpine Corsica (Vernié et al., 1986). The microstructural relationships in carbonate-rich layers suggest that epidote and blue amphibole are destabilized to form the peak paragenesis composed of aragonite + clinopyroxene + garnet + hematite + quartz + deerite (Fig. 6f).

5.2.2. Serpentine-continental crust

Samples of Stage#1 and Stage#2 metasomatic rocks were collected in the Monte Muffraje area (Fig. 2a). Carbonated metasomatic rocks forming at the expense of Stage#1 rocks display mm-banded fabric defined by the alternation of carbonate-rich and silicate-rich domains, the latter ones forming either continuous layers or isolated patches with thicknesses ranging from 50 µm to 5 mm (Fig. 4 in Piccoli et al., 2016). Silicate layers are mainly composed of Stage#1 clinopyroxene ± lawsonite (Lws1) ± quartz. Grain size ranges from µm to mm. *Carbonate* (calcite after aragonite) displays prismatic habit, with elongation axes oriented at a high angle to the main rock fabric, and it grew either with crack-seal texture or as pods within silicate-rich domains resulting in corrosion-like textures. Two *clinopyroxene* generations can be recognized by their different color in plane-polarized light and on the basis of microstructural evidence. The first generation (Cpx1), characteristic of Stage#1 metasomatism, comprises acicular crystals forming mm-sized fan-shape

aggregates. Cpx1 aggregates typically have embayed margins filled by carbonate. Remnants of single clinopyroxene fibers occur within the carbonate crystals (Fig. 7b). The crystallographic orientation of these remnants relative to the larger aggregates indicates that they formerly belonged to a single crystal. A second generation of clinopyroxene (Cpx2), characteristic of Stage#2 metasomatism, crystallized around Cpx1 (Fig. 7b) and is also present as isolated crystals in the carbonate domains. *Lawsonite* (Lws1) in metasomatic carbonated metasomatic rocks is found as large, inclusion-rich crystals (with dominant quartz, titanite, and rutile inclusions), whereas lawsonite in veins is inclusion free (Lws2, see also Section 5.2.4). *Garnet* is present in both carbonate and silicate-rich domains with euhedral to sub-euhedral habit. Poikiloblastic garnet includes mainly quartz, titanite, carbonate (calcite/aragonite) and lawsonite. Garnet also forms veins and pods together with carbonate. When present, *quartz* is granoblastic and is found as lens-shaped domains or rimming clinopyroxene aggregates together with garnet. Quartz can be either coeval with respect to carbonate and garnet (suggested by quartz rimming clinopyroxene together with garnet) or related to the retrograde evolution. Phengite is found as a late stage product crystallizing in fractures parallel to the rock foliation. Altogether, the microstructural relations suggest that a first paragenesis Cpx1 + Lws1 is replaced by a second paragenesis: aragonite + Cpx2 + garnet ± quartz.

The metasomatic overprint in this outcrop is pervasive, and the definition of a protolith rock is not obvious. Nevertheless, two samples preserve features suggesting that this metasomatic halo formed at the expense of continental basement rocks. Sample 1cor14-10d, collected within the metasomatic rind, appears unaffected by the typical patterns of Stage#1 or Stage#2 metasomatism, and is composed of blue amphibole, phengite, lawsonite and garnet. In this sample, garnet preserves a Mg-Fe core typical of the pre-Alpine HT paragneiss forming the continental basement slices (Martin et al., 2011), and is overgrown by a higher Ca-Fe component representative of the Alpine metamorphism (Fig. 6g; Table S2).

Sample 1cor14-10 g likely escaped Stage#1 metasomatism, but displays considerable evidence for Stage#2 carbonate metasomatism. The rock has a porphyroclastic fabric defined by jadeite porphyroclasts wrapped by a foliated matrix mainly consisting of Ca-carbonate, phengite, and quartz (Fig. 5f). The jadeite clasts range from 100 to 500 µm in size. Some portions of the jadeite crystals contain tiny ameboidal quartz inclusions (Fig. 7c). This kind of microstructure is commonly described in jadeite-bearing rocks formed by metamorphic conversion of former albite following the prograde reaction albite = jadeite + quartz (Compagnoni et al., 2012), and also occurs in the jadeite-bearing orthogneiss of the studied unit. The jadeite clasts are partially replaced by Ca-carbonate and late phengite, crystallizing along fractures (Fig. 7c,d), following the same microstructural patterns of carbonation observed for diopside in Stage#1 rocks (Fig. 5a in Piccoli et al., 2016). Ca-carbonate is the main constituent of the matrix, found as coarse-grained granoblasts. Granoblastic quartz forms lens-shaped domains. Late albite rims the margins of jadeite clasts and jadeite remnants in the carbonate matrix together with phengite. The presence of jadeite-bearing orthogneiss in the same area (west of Punta Caldane; Vitale Brovarone et al., 2011a) and the recognition of former pre-Alpine paragneiss in the metasomatic rind (this study), lead us to propose that this sample originally was a granitic or leucocratic igneous rock, belonging to a slice of pre-Alpine continental basement, and successively carbonated during the HP fluid-rock interactions (see Section 8). These observations suggest that in the Monte Muffraje area, the lower part of the metasomatic rind develops at the expense of a slice of pre-Alpine continental basement. This continental slice is probably the lateral termination of the thicker continental sliver that crops out to the south, in the area of Punta di Caldane.

5.2.3. Continental crust-Mesozoic metasediments

The first few meters of the metasediments overlying the continental crust consist of a chaotic sequence of carbonated mafic/ultramafic rocks.

In thin section, amphibole + chlorite cm-nodules embedded in a carbonate-rich layer display a continuous foliation marked by *chlorite* and *green amphibole*, whereas carbonate is interstitial. When present, *clinopyroxene* forms either small stubby neoblasts with deep green pleochroism or, more rarely, larger porphyroblasts with sharp optical zoning comprising brownish cores and deep green pleochroic rims (Fig. 5c in Piccoli et al., 2016). Green pleochroic clinopyroxene is also present as inclusions in amphibole crystals together with calcite. Therefore, two generations of clinopyroxene are distinguished: Cpx1 porphyroblast cores and Cpx2 rimming Cpx1 or forming smaller neoblasts. Based on the microstructural relationships, only Cpx2 is considered in equilibrium with the paragenesis green amphibole + chlorite + carbonate. *Blue amphibole*, *garnet* and *phengite* may also be present in some samples.

Carbonate-quartz-rich rocks are also present within the carbonated mafic/ultramafic sequence. These rocks display mm-banded fabric of alternating carbonate-rich and silicate-rich domains (quartz, clinopyroxenes and blue amphibole, Fig. 3c3). A continuous schistosity (Passchier and Trouw, 2005) is marked by phengite, clinopyroxene, blue amphibole, and epidote preferred orientation. Grain size ranges from μm to mm. *Clinopyroxene* is found in sub-euhedral prismatic crystals, with deep green pleochroism. No optical zoning is observed in the clinopyroxene (Fig. 6h). *Garnet* is present in mm-sized crystals, colorless in thin section. Some samples display weakly zoned, inclusion-rich garnet (pink core and colorless rim) with dominant quartz, calcite/aragonite, phengite, and zircon inclusions. More retrogressed samples display idio-blastic crystals of *blue amphibole* (mm in size), with a lavender-blue pleochroism. *Phengite* wraps around garnet porphyroblasts. *Epidote* is present in prismatic, colorless crystals, except for local brown allanitic cores. *Lawsonite* pseudomorphs may also be present. *Tourmaline* is an accessory mineral. Considering the more homogeneous mineralogy and the microstructural evidence, we propose that only one equilibrium paragenesis is present: carbonate + garnet + phengite $\pm$ clinopyroxene $\pm$ blue amphibole.

5.2.4. Vein material

Several types of veins are found in association with the carbonated metasomatic systems studied herein. In all vein types, the carbonate phase is always compositionally pure Ca-carbonate with a rod-shaped habit orientated at a high angle to the vein wall. The vein crack-seal texture suggests that the veining event is linked to fluid-overpressure and hydrofracturing (Ramsay, 1980). This is consistent with the observation of hydraulic breccias within the metasomatic rind and suggests brittle deformation during the fluid-rock interactions at HP conditions (Piccoli et al., 2016).

5.2.4.1. Carbonate veins. This kind of vein is characterized by elongated carbonate crystals and small clasts of wallrock inclusions aligned parallel to the vein wall (Fig. 8a), features typical of crack-seal (Ramsay, 1980). No vein selvage is observed in the wallrock. This kind of vein is found within the metasomatic rind along the serpentinite-Mesozoic metasediments contact and along the continental crust-metasediments contact (see Section 5.2.3).

5.2.4.2. Carbonate + omphacite veins. These are elongate, blocky veins (Oliver and Bons, 2001) with smaller omphacite crystals seeded on the wallrock and outgrown by larger elongate calcite crystals (Figs. 3b3

and 8b). The observation of the growth competition indicates that crystals grew into a fluid-filled crack, with a crack-seal mechanism (Oliver and Bons, 2001 and references therein). This kind of vein displays a selvage in which the wallrock diopside has omphacite rims. The vein selvage is also characterized by the presence of phengite (Fig. 8b). However, microstructures do not establish if phengite was coeval to the carbonate precipitation in the vein. This kind of vein is found within the metasomatic halo along serpentinite-Mesozoic metasediments contacts.

5.2.4.3. Carbonate + Lawsonite $\pm$ diopside. As in the carbonate + omphacite veins, calcite crystals are elongated and parallel to the vein wall (Fig. 3b4). *Lawsonite* is present as poikilitic porphyroblasts together with quartz, graphite, and rare titanite and calcite inclusions, or as small (μm in size) inclusion-free crystals (Fig. 8c). *Lawsonite* is optically zoned with pinkish zones that correspond to high Cr content (Table S2; Fig. 8d). When present, clinopyroxene is found as small ($<100\mu\text{m}$) prismatic crystals overgrowing lawsonite crystals (Fig. 8c). This kind of vein has been observed within the metasomatic rind along the serpentinite-Mesozoic metasediments and the serpentinite-continental crust contacts.

6. Mineral chemistry

6.1. Clinopyroxene

The compositional evolution of clinopyroxene displays common patterns in samples from different tectonostratigraphic positions. Fig. 9a shows jadeite-aegirine-QUAD ternary diagrams for clinopyroxenes in Stage#1 rocks (unaffected by Stage#2, sample 1cor12-11P) and Stage#2 carbonated metasomatic rocks from the three types of tectonostratigraphic contacts (classification after Morimoto, 1989). In general, Stage#1 clinopyroxene compositions (in both Stage#1 rock unaffected by carbonate-metasomatism and relict Cpx1 in Stage#2 rocks) plot in the QUAD field and are diopside (CaO ~24 wt%, MgO ~12 wt%, FeO ~8 wt%). Most Stage#2 zoned clinopyroxene crystals (Cpx2) from samples overlying serpentinites have Na-Al enrichment with respect to the core (Cpx1), and omphacitic compositions. However, some samples have Na-Fe³⁺ enrichment in the rim, and plot in the aegirine-augite field. Clinopyroxene in carbonate veins is omphacite, whereas in carbonate + lawsonite veins it is diopside. Clinopyroxene in carbonated metasomatic rocks formed at the expense of metasediments has high Mn content (up to ~2–3 wt%, Table S2). Mn may be present in the core as well as in the newly crystallized omphacite (Fig. 7a and h, respectively). Chromium in clinopyroxene occurs in significant amounts only in two samples: cor13-21d and 1cor14-6a. In sample cor13-21d, Cpx1 is an Al-rich diopside with higher Cr content (~1 wt%, Table S2) than Cpx2 in the rim (~0.6%). The plausible ultramafic origin of this sample has been discussed in Piccoli et al. (2016) based on bulk-rock trace element analysis. In sample 1cor14-6a, clinopyroxene is zoned; Cr rich domains have as much as ~1 wt% Cr₂O₃.

6.2. Garnet

Fig. 9b reports the garnet composition for the carbonated metasomatic rocks in a grossular-almandine-spessartine ternary diagram; the pyrope content is always very low (X_{Mg} ranging from ~0 to 0.03) and

Fig. 6. Thin section photomicrographs depicting the microstructural characteristics of both unaltered and metasomatic rock. **a)** Garnet + phengite level in metachert (sample cor16-42d). **b)** Quartz-carbonate-rich metasediment (sample 1cor12-20c). **c)** Microstructural relationship between two clinopyroxene generations and carbonate (sample 1cor12-20d). Note that Cpx2 forms euhedral crystals in textural equilibrium with carbonate. **d)** Snowball garnet with sigmoidal-shape zoning (sample 1cor14-2). **e)** Garnet with sieve texture and optical concentric zoning (sample 1cor14-2). Note the textural equilibrium between epidote and quartz. **f)** Epidote being rimmed and replaced by clinopyroxene (sample 1cor14-6a). Hematite is found as large prismatic crystals. **g)** Atoll-like garnet in sample 1cor14-10d together with BSE image showing chemical zoning. The dark zone is Mg rich and is a remnant of pre-Alpine HT metamorphism. (see also Martin et al., 2011) **h)** Clinopyroxene and ferroglaucophane in metasomatic marble overlying the continental crust (sample cor13-21b).

Fig. 8. Photomicrographs of vein materials. **a)** Carbonate crack-seal in mafic clast (sample cor13-27c). Vein carbonate is prismatic (rods are highlighted by dashed white lines) and oriented at high angle to the rock foliation, marked by chlorite preferred orientation. Ankerite porphyroclast is wrapped around by phengite (marked with dotted green lines). **b)** Omphacite + carbonate vein and vein selvage (sample 2cor14-3b). Omphacite crystals seed on the wallrock and are outgrown by calcite. Note the occurrence of well-crystallized phengite crystals in the vein selvage. **c)** Lawsonite + carbonate vein (sample 1cor14-RM). Small prismatic clinopyroxene crystals crystallize around lawsonite. **d)** Detail of lawsonite in a lawsonite + carbonate vein showing the optical zoning in lawsonite given by high Cr content. (For interpretation of the references to colour in this figure legend, the reader is referred to the web version of this article.)

the andradite component is large only in garnet cores from sample 1cor14-6a and in garnet from sample 1cor14-12b (Table S2). Garnet in samples along the serpentinite/metasediment contact is zoned. In most cases, garnet zoning corresponds to an increase in Ca-Fe relative to Mn (Fig. 10a,b). In some cases, (Fig. 10c,d) the rim has a sharp enrichment in the spessartine component (with X_{Sps} rising from ~21 to ~43%, X_{Alm} decreasing from ~53 to ~34%, and X_{Grs} remaining stable, see also sample

1cor12-20d in Table S2). Fig. 10d also shows an electron microprobe map of garnet from sample 1cor12-20d: together with the increase in MnO, the garnet rim also displays oscillatory zoning in Cr_2O_3 (Cr_2O_3 up to ~0.15 wt%). In this same sample, smaller, euhedral crystals have a more homogeneous composition (X_{Alm} ~25%, X_{Sps} ~36%, X_{Grs} ~39%). Garnet in sample 1cor14-12b displays complex compositional zonation. Mn rich garnet preserved around quartz inclusions has an average

Fig. 7. Backscattered electron (BSE) images and EDX maps obtained by SEM depicting microstructural evidences of bulk composition changes during metasomatic events. **a)** BSE image of a skeletal clinopyroxene in sample 1cor12-20d. The image well shows the oriented remnants of Cpx1 preserved in calcite crystals, thus suggesting dissolution of Cpx1 and precipitation of carbonate + Cpx2. **b)** Fibrous clinopyroxene aggregate with embayed rims (sample cor13-22c). The small, aligned fragments preserved in carbonate crystal have Cpx1 composition. The microstructure suggests dissolution of Cpx1 and precipitation of carbonate + Cpx2. **c)** BSE image showing a detail of a jadeite clast with quartz inclusions, being replaced by carbonate and late stage phengite. **d)** EDX map of jadeite clast replaced by carbonate and phengite (sample 1cor14-10 g). Some remnants of jadeite are preserved in the carbonate matrix. **e)** BSE image of complex chemical zonation in garnet (sample 1cor14-12b). Note that garnet around carbonate inclusion is dark grey, whereas it is bright gray when far from carbonate inclusions, or around quartz inclusions. The transition between chemical zones is sharp. **f)** EDX maps of garnet around quartz and carbonate inclusions. Chemical zoning is linked to different content in Mn and Ca. Garnet zones free of carbonate inclusions always have higher Mn content, whereas garnet around carbonate has higher Ca content. The former is interpreted as out of equilibrium composition, whereas Ca rich garnet crystallizes during the metasomatic stage. **g)** BSE image clinopyroxene and carbonate inclusion in garnet. Arrows indicate the high Mn content in garnet far from calcite inclusions. The preservation of the pre-metamorphism garnet shows the crystal failed in achieving the equilibrium with the matrix. **h)** EDX maps of clinopyroxene in garnet showing garnet compositional changes associated with mineral inclusions. Garnet in contact with clinopyroxene is Ca rich. Moreover, clinopyroxene has high Mn content suggesting that Mn is exchanged between garnet and clinopyroxene.

Fig. 9. Mineral chemistry. **a)** Ternary diagram for clinopyroxene compositions. For each sample, Cpx1 and Cpx2 are reported with the same color, but different symbols (circle and diamond respectively). **b)** Ternary diagram for garnet compositions. Analyses of garnet core/mantle/rim of the same sample are reported with same color and different symbol (circle, diamond, square, respectively). **c)** Phengite composition plotted on the Si vs. (Fe + Mg) diagram. The solid line represents the ideal celadonic substitution. Si is given as atoms per formula units (a.p.f.u.) on the basis of 11 oxygens.

composition of $X_{\text{Alm}} \sim 25\%$, $X_{\text{Sps}} \sim 55\%$, $X_{\text{Grs}} \sim 15\%$, $X_{\text{Adr}} \sim 5\%$, whereas Ca-richer garnet around calcite or clinopyroxene has an average composition of $X_{\text{Alm}} \sim 20\%$, $X_{\text{Sps}} \sim 20\%$, $X_{\text{Grs}} \sim 55\%$, $X_{\text{Adr}} \sim 15\%$. Matrix garnet in carbonated metasomatic rocks formed at the expense of continental

basement rocks (samples cor13-22a and cor13-22c) has a Fe-Mn rich composition ($X_{\text{Alm}} \sim 20\%$, $X_{\text{Sps}} \sim 49\%$, $X_{\text{Grs}} \sim 31\%$), while anhedral crystals or garnet in veins is grossular rich ($X_{\text{Alm}} \sim 2.5\%$, $X_{\text{Sps}} \sim 1\%$, $X_{\text{Grs}} \sim 96.5\%$). Garnet in samples overlying continental basement

Fig. 10. Garnet compositional zoning. **a-b**) BSE image and EDX map of zoned garnet from sample 1cor14-2. Garnet has a Mn-rich core and a Ca-Fe-rich rim, this latter in equilibrium with carbonate. **c**) BSE image of zoned garnet from sample 1cor12-20d. The white box indicates the location of the microprobe map. **d**) Microprobe maps highlighting the presence of Mn zoning together with Cr oscillatory zoning in the rim (maps treatment with XMapTools software, Lanari et al., 2014).

(cor13-21b and cor13-27e) are unzoned with X_{SpS} varying from one sample to another (Fig. 9b and Table S2).

6.3. Phengite

Potassium-rich white micas are phengites (Table S2), with Si content ranging between 3.5 and 3.6 atoms per formula unit (a.p.f.u.). All phengites have K around 1 a.p.f.u and quite homogenous Fe^{2+} and Mg contents (~ 0.1 and ~ 0.5 a.p.f.u., respectively), with the exception of sample 1cor14-10 g which has lower Fe-Mg. Fig. 9c shows phengite compositions plotted on the Si vs. ($\text{Fe}^{2+} + \text{Mg}$) (a.p.f.u.) diagram. Only phengite in samples cor13-21b and 1cor14-10 g approach the ideal Tschermak substitution, whereas the other samples plot above the ideal substitution line. The high Mg-Fe contents might result from a partial substitution of Al with Fe^{3+} , quite common in HP terranes (Miyashiro and Shido, 1984). In sample cor13-22c, phengite crystals in the matrix have lower celadonite content than phengite replacing clinopyroxene, suggesting requilibration of the matrix crystals at a lower P condition.

6.4. Amphibole

Carbonated metasomatic rocks formed at the top of continental basement contain abundant sodic amphibole ranging in composition from glaucophane to ferroglaucophane (Fig. 11a). Green amphibole in the chaotic mafic/ultramafic sequence has tremolite composition (sample cor13-21d). Sodic amphibole in samples overlying the serpentinite basement has composition ranging from riebeckite to Mg-riebeckite, whereas green amphibole is actinolite (Fig. 11a,b, classification after Leake et al., 1997). Amphibole structural formula is calculated based on 23 oxygens and with $\text{Fe}^{2+}/\text{Fe}^{3+}$ estimation assuming 13 cations.

6.5. Epidote

Epidote composition is given using the ternary classification from Franz and Liebscher (2004). As Mn-bearing compositions are common, the ternary diagram was constructed with clinozoisite, epidote and

Fig. 11. Mineral chemistry. **a)** Classification diagram for sodic amphiboles; **b)** Classification diagram for calcic amphiboles. Classification after [Leak et al. \(1997\)](#).

piemontite endmembers. In sample 1cor12-20d, epidote has high Mn and Fe ($X_{Cz} \sim 0$, $X_{Ep} \sim 0.5$ and $X_{Pie} \sim 0.5$; Table S2), but in other samples Mn-rich epidotes ($X_{Pie} \sim 0.7$) and piemontite ($X_{Pie} \sim 1$) are found (samples cor13-28c and 1cor14-5). In sample cor13-27e, epidote is Fe rich but Mn poor ($X_{Cz} \sim 0.6$, $X_{Ep} \sim 0.4$). Generally, epidote overgrowing lawsonite is related to retrograde evolution and has high clinozoisite content (X_{Cz} ranging from ~ 0.7 to ~ 0.9). In sample 1cor14-6a, epidote has elevated Cr_2O_3 up to ~ 2 wt%.

6.6. Lawsonite

Lawsonite in carbonated metasomatic rocks is close to pure composition. In some carbonate + lawsonite veins, it is Ti-bearing (TiO_2 up to ~ 1 wt%, Table S2) and/or Cr-bearing (Cr_2O_3 up to ~ 3.25 wt%, sample cor13-29, Table S2).

6.7. Carbonate

Carbonate is always nearly pure calcium carbonate, with the only exception being iron-rich carbonate nodules found in carbonated mafic/ultramafic lithologies together with actinolite-chlorite-rich assemblages.

6.8. Deerite

Deerite is present only in sample 1cor14-6a. It departs significantly from end member composition and has considerable MnO (~ 2.4 wt%), MgO (~ 2 wt%), and TiO_2 (~ 0.8 wt%), together with minor Cr_2O_3 (~ 0.5 wt%) and Al_2O_3 (~ 0.2 wt%).

7. Discussion

Lithological boundaries, together with fracture sets or permeable layers, are structural features that facilitate fluid channelization (e.g. [Oliver, 1996](#); [Oliver and Bons, 2001](#); [Zack and John, 2007](#); [Ague, 2014](#); [Bebout and Penniston-Dorland, 2016](#)). The multiple metasomatic products (Stage#1 and Stage#2) described in this study formed along the main lithological boundaries of the subducted section of oceanic/transitional lithosphere preserved in the lawsonite eclogite-facies, i.e. the basal unconformity separating Mesozoic sediments from the underlying

rocks. Consequently, these interfaces acted as major fluid conduits for a protracted period of time, from prograde to peak conditions and probably during early stages of exhumation as well. Field, microstructural and geochemical data ([Piccoli et al., 2016](#); this study) strongly indicate that carbonate minerals (mainly Ca-carbonate) were involved in these protracted fluid-mediated processes, including possible carbonate dissolution/decarbonation during Stage#1, and strong reactivity between the silicate minerals and carbon-bearing fluids during Stage#2. These processes did not take place in-situ in closed systems (e.g., dissolution-precipitation; [Ferrando et al., 2017](#)), but was mediated through large-scale reactive fluid flow involving transient carbon mobilization and successive carbonation of initially carbon-free lithologies. The high lithological variability of the metasomatized suites provides a good means to assess: (i) the reactivity of different rock types to deep carbon-bearing fluids and rock carbonation; (ii) the fluid composition; and (iii) the fluid sources and the possible scale of the reactive fluid flow. These three points will be discussed below.

7.1. Protolith rocks

7.1.1. Evidence for extreme transformation of Mn-metacherts

In the field, incomplete metasomatic transformation and preservation of partially replaced Mn-metacherts is only locally found ([Fig. 3a4](#)) and characterized by the progressive overgrowth of primary Mn-rich garnet by metasomatic Ca-rich garnet. Similar trends are also observed in carbonated metasomatic rocks for which a protolith is difficult to identify in the field. Mn-rich garnet in some carbonated metasomatic rocks is found either in the core, rimmed by Ca-rich garnet, or as patchy compositional zones controlled by local equilibria between relict (e.g. quartz) and metasomatic (e.g. carbonate) phases (see [Figs. 7f,g,h](#) and [10a,b](#)). Even in the latter case, microstructural relationships indicate that the Mn-rich garnet was the stable garnet prior to metasomatism. The local occurrence of annuli of high Mn near the rim may result from garnet resorption ([Kohn and Spear, 2000](#)). Alternatively, external fluid infiltration may add Mn to the system, or enhance the breakdown of Mn-rich phases such as epidote and the internal redistribution of Mn in the rock (piemontite or Mn-bearing epidote is very common in Alpine metacherts, e.g. sample 1cor14-5c; [Yang and Rivers, 2001](#)). The observed epidote breakdown reaction in sample 1cor14-6a, and the presence of Mn-rich epidote (MnO up to ~ 22 wt%)

in some of the carbonated metasomatic samples (e.g. sample 1cor12-20d; cor13-28c) support the hypothesis of redistribution of Mn inside the rock during fluid infiltration. Moreover, in some cases the Mn enrichment in the garnet rim is associated with Cr-oscillatory zoning. Chromium zoning cannot be explained by the breakdown of an internal source (i.e., Cr-bearing phases are absent). Instead, it requires the infiltration of an external fluid, likely derived from mafic/ultramafic rocks. All together, these features indicate that Mn-rich garnet can be used as a marker for metasomatized metacherts by both preservation of relict Mn-rich garnet cores, or by fluid-mediated redistribution of Mn in the rock and growth of Mn-rich garnet rims.

An additional marker for carbonation of metacherts may be the presence of deerite-bearing assemblages, which are usually described in carbonate-free, metamorphosed metacherts from Alpine Corsica (Vernié et al., 1986) as well as other blueschist-facies (Franciscan, Alps, Turkey, the Aegean, and New Caledonia; Muir Wood, 1979) and eclogite-facies terrains (Tianshan, Zhang et al., 2017). We propose that deerite and hematite observed in sample 1cor14-6a are inherited from the protolith and indicate that, in Punta Favalta, Mn-rich metacherts were carbonated during subduction metasomatism.

7.1.2. Evidence for extreme transformation of mafic and felsic pre-Alpine basement

Two key observations allow identification of the pre-Alpine continental basement rocks as a protolith for some extremely metasomatized rocks. Martin et al. (2011, 2014) showed the preservation of pre-Alpine, Mg-Fe-rich HT garnet in Stage#1 metasomatic rocks is a marker of replacement of former (carbonate free) mafic paragneiss. In carbonated metasomatic rocks, no evidence for the preservation of pre-Alpine HT garnet was found. Nevertheless, this relict garnet was found in a lens of mafic schists within the metasomatic rind of Mt. Muffraje, which escaped both Stage#1 and Stage#2 metasomatism (1cor14-10d, Fig. 6g). Secondly, from the same outcrop, extremely carbonated rocks (sample 1cor14-10 g) contain relicts of jadeite porphyroblasts that likely formed by prograde transformation of large albite crystals, as observed in orthogneiss unaffected by metasomatism in the San Petrone continental basement slices. This observation suggests that the continental crust slice in this area also contained jadeite-bearing orthogneiss. Alternatively, the presence of albitic feldspar later converted to jadeite in carbonate-bearing rocks may be explained by an arkosic detrital component in the original sediment. Silicoclastic metasediments are found throughout the HP units of Alpine Corsica, known as the San Pietro di Tenda metasedimentary formation, where arkosic layers within basaltic lavas have been reported (e.g., Caron and Delcey, 1979; Caron et al., 1981; Péquignot et al., 1984; Lahondère, 1996). However, even if the origin of the rock remains unclear (metagranite or metaarkose), the microstructures show jadeite being replaced by carbonate (Fig. 7d), thus supporting the high reactivity, at HP conditions, between carbon-bearing fluids and clinopyroxene.

The above evidence documents that in this area, HP fluid-mediated carbonation affected both mafic paragneiss and felsic orthogneiss belonging to a continental basement slice. Notably, the jadeite-bearing sample indicates that carbonation also occurred without a precursor Stage#1 diopside-lawsonite metasomatic stage, and represents the first evidence for carbonation of metafelsic rocks during HP-LT metasomatism. Thus, HP carbonation by infiltration of carbon-bearing aqueous fluids may be an important process for deep carbon sequestration in continental subduction and collisional settings.

7.1.3. Evidence for metasomatism and carbonation of ultramafic rocks

The serpentinite basement of the San Petrone unit does not show significant metasomatic overprinting or evidence for carbon-bearing fluid infiltration, such as carbonate, talc, and amphibole crystallization. This suggests that either this lithology was not reactive, or fluids did not infiltrate it.

In the Punta Ventosa and Punta Caldane areas, chaotic sequences of mafic/ultramafic material embedded in carbonate matrix overlie the continental crust sliver and show evidence for HP metasomatism. The mineral assemblage (chlorite, actinolite, and minor clinopyroxene and ankerite) and whole rock geochemical signature of these rocks (Piccoli et al., 2016) demonstrate their mafic/ultramafic origin. Sedimentary breccias containing ultramafic/mafic clasts are commonly described in active slow-spreading ocean basins and their metamorphic equivalents (Lagabriele and Cannat, 1990; Lagabriele et al., 2015), and are the likely protolith for these chaotic sequences. The metasomatism of metasedimentary breccia containing serpentinite clasts transformed into carbonate + chlorite + actinolite assemblages could potentially be caused by an increase in X_{CO_2} during infiltration of external carbon-bearing fluids, as suggested by abundant carbonate veins, crack-seals, and hydraulic breccias (Figs. 4f, 8a).

The above evidence clearly shows that mafic/ultramafic rocks can be extremely reactive with carbon-bearing fluids at HP conditions, yet the serpentinite basement is uncarbonated. This lack of carbonation might be linked to the fluid chemistry or to low permeability to fluid infiltration. In the first hypothesis, the X_{CO_2} of the fluid ($X_{\text{CO}_2} = \text{CO}_2/(\text{H}_2\text{O} + \text{CO}_2)$) could have been too low to destabilize the antigorite. Considering the observed co-stability of lawsonite and aragonite in Stage#2 rocks, the reaction lawsonite + aragonite + quartz = grossular sets a lower limit of X_{CO_2} at 0.00125 for the fluid in equilibrium with these rocks (Fig. S2a; see Supplementary material for modeling conditions). For this value of X_{CO_2} , antigorite in the underlying serpentinite should be destabilized ($X_{\text{CO}_2} < 0.001$ in Fig. S2a), whereas diopside in the Stage#1 rocks should be stable ($X_{\text{CO}_2} < 0.004$, Fig. S2). This observation, together with the local carbonation of ultramafic material within the sedimentary pile, suggests that the asymmetry of the metasomatic rinds was most likely due to permeability contrasts along lithological boundaries rather than fluid chemistry. Actually, the existence of permeability contrasts between two adjacent lithologies has the effect of diverting the fluid flow toward higher permeability region, leading to asymmetrical distribution of reaction progress (Breeding et al., 2003; Ague, 2007). Consequently, we propose that large gradients in fluid fluxes, resulting from permeability contrasts between litho-tectonic rock packages, were responsible for the formation of strongly asymmetric metasomatic front. These permeability contrasts also probably controlled fluid flow channelization at the regional scale along at least 10–12 km of subducted transitional lithosphere exposed in the San Petrone unit (See Section 7.3 for further discussion).

7.2. Fluid composition and sources

The carbonated metasomatic rocks display a complex geochemical signature that suggests a multi-source nature for the metasomatic fluids, by analogy to what has been proposed by previous studies on Stage#1 metasomatic rocks (Martin et al., 2011; Vitale Brovarone et al., 2014b).

The most striking geochemical features of Stage#2 are enrichments in Ca, C (Ca-carbonate), Na (Na-clinopyroxene), and Cr (oscillatory zoning in garnet, lawsonite, and clinopyroxene; Cr-rich lawsonite in veins). Ca enrichment during carbonation happens via carbonate precipitation and silicate replacement, thus implying a combined supply of Ca and C. Processes of carbonate dissolution in aqueous fluids are expected to release fluids with 1:1 M Ca:CO₂ ratios (Ague and Nicolescu, 2014) that would easily explain the reprecipitation of Ca-carbonate rich assemblages (Piccoli et al., 2016; this study). Carbonate-rich rocks, such as metasediments, may therefore be considered as one among multiple fluid sources. Moreover, the carbon isotopic signature of carbonates (−0‰ vs. PDB) indicates that the source of C was likely marine metasediments (Piccoli et al., 2016), thus further supporting this interpretation. Considering that locally Stage#1 develops within carbonate-bearing Mesozoic metasediments, it is plausible that part of the dissolved carbonate during Stage#1 is then transported for short distances and re-

Fig. 12. a) Conceptual model of the genesis, migration and evolution of the metamorphic fluids responsible for HP rock carbonation. Aqueous fluids are released by lawsonite and antigorite breakdown at depth of ca. 100 km (1). Part of the fluids that migrate upward can be channelized in permeable metasomatic horizons formed along major discontinuities like lithological boundaries (2). Aqueous fluids interact with carbonate-bearing rocks (altered oceanic crust and metasediments) at condition of high carbonate solubility (Fig. 12b), leading to carbonate dissolution and fluid enrichment in Ca-C and alkali. Fluids equilibrated at depth, will become oversaturated in carbonates during decompression and will precipitate carbonates through veining and/or silicate dissolution, which increases the X_{CO_2} of the fluid favoring carbonate precipitation (3). **b)** P-T diagram reporting the predicted P-T path for active subduction (D80 model, Syracuse et al., 2010) together with the main fluid-releasing reactions for basalt + H₂O (lawsonite breakdown) and peridotite + H₂O systems (antigorite + brucite, antigorite and chlorite breakdown) (Poli and Schmidt, 2002). Dashed red lines indicate the carbon contours in parts per million for aqueous fluid saturated in CaCO₃ (Kelemen and Manning, 2015). The dashed black arrow indicates the trajectory for a cold subduction, whereas the blue arrow indicates the upslope fluids path. This diagram shows how a fluid, equilibrated with carbonates at depth, will become oversaturated in carbonate when decompressing. (For interpretation of the references to colour in this figure legend, the reader is referred to the web version of this article.)

precipitated. Nevertheless, this hypothesis cannot explain the observed carbonation of precursor rocks that were originally carbonate-free.

Enrichment in Ca and C is in most cases accompanied by the formation of Na-rich clinopyroxene (Cpx₂), such as omphacite (Na-Al) or aegirine-augite (Na-Fe³⁺) depending on the nature and oxidation state of the precursor rock. Considering the very low Na content in Stage#1 metasomatic rocks because of Na mass loss after Stage#1 metasomatism (–80%, Vitale Brovarone et al., 2014b), we suggest that Na mass gain occurred during carbonate metasomatism and fluid infiltration, as also indicated by omphacite formation in Stage#2 carbonate veins (Fig. 3b3). This evidence provides a robust constraint on the circulation of Na-C-Ca-bearing fluids. Sodium mass gain during HP metasomatism is widely reported in different geological settings (Beinlich et al., 2010; Spandler and Hermann, 2006; Galvez et al., 2013; Ague and Nicolescu, 2014; Taetz et al., 2016) and water-rich alkalis- and carbon-bearing fluids are documented by fluid inclusion studies in eclogite-facies oceanic suites (Monviso and Tauren Window; Philippot and Selverstone, 1991; Selverstone et al., 1992).

As is the case for Ca and C, Na can derive from devolatilization reactions in metasediments. However, if Na were derived from the metasediments, K, Rb and Ba enrichment would also be expected. Moreover, a purely metasediment-derived fluid would be inconsistent with the oxygen isotopic signature of metasomatic carbonate (~10‰ V-SMOW; Piccoli et al., 2016) and with Cr-rich minerals (clinopyroxene, lawsonite and garnet; this study), characteristics that point to mafic/ultramafic sources like metagabbros and/or serpentinite. Alternatively, altered metamorphic rocks like metabasalts are possible source of Na, Ca, C, and Cr together with isotopically light oxygen.

Experimental studies consider Cr as fluid immobile (Kogiso et al., 1997; Green and Adam, 2003). Cr enrichment might be explained by local mobility by diffusion (Rubatto and Hermann, 2003) or residual enrichment. Nevertheless, Cr oscillatory zoning in Stage#2 minerals such as garnet, and the very low content of Cr in Stage#1 rocks, rule out the hypothesis of local Cr diffusion. Moreover, the formation of Cr-rich lawsonite in carbonate veins (samples cor13–29c, 1cor14-RM), clearly document the presence of this element in the circulating fluids at HP conditions.

High Cr contents and oscillatory zoning in eclogite-facies fluid-mediated rocks such as veins have been reported in several settings including the Stage#1 metasomatic rocks studied in the San Petrone unit. These features are generally interpreted as tracers of mafic/ultramafic-derived fluids equilibrated with metagabbro and/or serpentinite (e.g. Tsujimori et al., 2006; Spandler et al., 2011; Tsujimori and Ernst, 2014; Angiboust et al., 2014; Vitale Brovarone et al., 2014b). Lawsonite breakdown in metagabbros may be a possible source for low $\delta^{18}\text{O}$, Cr-bearing aqueous fluids. Nevertheless, metagabbros are not observed in the San Petrone unit; thus, we consider it unlikely that this lithology was a local fluid source. Another possible source of low $\delta^{18}\text{O}$ aqueous fluids is the breakdown of antigorite serpentinite, which is expected to happen through successive stages from 400 to 700 °C and 1 to 3 GPa (e.g., Ulmer and Trommsdorff, 1995; Rüpke et al., 2004). Serpentinite-derived fluids can account for the observed Na and Cr enrichment. For example, Scambelluri et al. (1997) reported high salinity fluid inclusions in eclogitized hydrous peridotite (Erro-Tobbio peridotite, Western Alps). The key point to emphasize is that an external and deeper source of water-rich fluids (metabasalts, metagabbros and/or serpentinite) must

have been present to account for the mafic/ultramafic geochemical fingerprint of the carbonated metasomatic rocks.

7.3. Fluid evolution migration pathways

The aqueous nature of the infiltrating fluid, together with the dominant low $\delta^{18}\text{O}$ isotopic signature of carbonate in Stage#2 metasomatic rocks points to ultramafic/mafic rocks (serpentinite and metabasites) as the main source of water. However, major dehydration reactions in hydrated mafic/ultramafic systems are not predicted at the P-T conditions of the San Petrone unit (~500 °C and 2 GPa), with the exception of partial antigorite breakdown in the presence of brucite (Trommsdorff and Evans, 1980; Scambelluri et al., 1995). More significant dehydration reactions in these systems are expected to take place at higher P-T metamorphic conditions, in the range of 700 °C and 3 GPa, including lawsonite breakdown in metabasite and the antigorite-out reaction in serpentinite (Fig. 12a,b). That is to say, fluid release reactions would happen in a zone between ~10–30 km deeper than the estimated conditions for metasomatism and carbonation in the study area (Fig. 12a,b). Fluids produced in the deeper part of the slab can then migrate upslope along major discontinuities/permeable layer (Faccenda, 2014; Wilson et al., 2014), and cause metasomatism at lower P conditions (e.g., Bebout and Barton, 1993; Herms et al., 2012; Angiboust et al., 2014). In Section 7.1.3, we concluded that, in our case study, the serpentinite was less permeable than the overlying metasedimentary or gneissic rocks, and this permeability contrast favored fluid channelization along the contact between the serpentinite basement and the overlying metasediments. This conclusion is supported by several studies demonstrating that fluids are channelized by permeable layers or structural features like fold axes, leading to high metamorphic fluid fluxes (i.e. Rye et al., 1976; Yardley and Lloyd, 1995; Skelton et al., 1995; Ague, 2014). Moreover, the fluid-rock interaction during Stage#1 may have enhanced the permeability of the metasomatic zone (Yardley and Balashov, 1998) with respect to the overlying metasediments, thus further favoring the channelization of fluids along this permeable layer. This happened along a major interface of the subducting slab, thus allowing slab-parallel fluid flow along several kilometers (at least 10–12 in the study area, and probably more). Extremely channelized fluid flow at regional scale is also consistent with the lack of pervasive isotopic homogenization at the scale of the Corsican metaophiolite (Miller et al., 2001).

Compared to analogous models in mélange-type plate interfaces (Bebout and Barton, 1989, 1993; Bebout and Penniston-Dorland, 2016), our study points to two important conclusions. Firstly, the structural localization of metasomatism along the basal unconformity of the subducted metasedimentary pile suggests an important role exerted by major inherited lithospheric lithological discontinuities for the channelization and upward migration of deep fluids. This does not contradict the possible equivalent role played by the plate interface, but suggests that fluid can be channelized at different levels within the subducting slab. Secondly, the results of the study of carbonated metasomatic rocks demonstrate that the composition of the fluid responsible for metasomatism derived by multiple sources from mafic/ultramafic rocks as well as metasediments. The evidence for the multi-source nature of HP fluid allows us to construct an updated model for the evolution of deep fluids by reactive fluid flow.

The model is illustrated in Fig. 12a, which summarizes the main stages of fluid release and fluid-rock interactions bearing on the origin of HP carbonation in the units of Alpine Corsica. Lawsonite and antigorite breakdown releases large amounts of aqueous fluids with light $\delta^{18}\text{O}$ signatures (“1” in Fig. 12a) and characteristic mantle tracers such as Cr. Some fraction of these fluids can be channelized along the basal unconformity of the metasedimentary pile (“2” in Fig. 12a). Channelized fluid flow, parallel to the slab and along a down-T, down-P geothermal gradient as well as along lithological contrasts gives the necessary chemical potential for reactive fluid flow (Fig. 12b). When water-rich fluids initially infiltrate altered

oceanic crust and/or metasediments, they can dissolve carbonates, becoming enriched in Ca, C, as well as leak other elements like Na (“2” in Fig. 12a, and b).

Successively, carbon-bearing fluids infiltrate silicate-rich rocks and drive carbonation reactions. During HP carbonation, carbonates are precipitated in veins and silicates are dissolved and replaced by carbonates (“3” in Fig. 12a). Together with the clear evidence for the infiltration of carbon-bearing fluids, the dissolution of silicates during this phase of fluid-rock interaction might have enhanced a positive feedback for carbonation. As recently proposed by Tumianti et al. (2017), silicate dissolution at HP conditions may be accompanied by the formation of organic complexes in the fluid, which promotes a decrease of water activity and an associated increase of X_{CO_2} . This increase of X_{CO_2} can further favor the stability of carbonate mineral and potentially, enhance carbonation reactions.

The above model is built on observations from an Alpine-type slab characterized by slow-spreading and transitional lithosphere. Its applicability to the global range of subducting slabs will require additional work and the consideration of the specific nature of individual subducting plates, thermal regime, and the associated metasedimentary suites. Nevertheless, our findings, together with reported carbonation processes in greenschist (Nishiyama, 1990; Skelton et al., 1997), blueschist (Kleine et al., 2014) and eclogite facies terrains (Piccoli et al., 2016; Scambelluri et al., 2016; this study), demonstrate that rock carbonation may have a larger impact on the carbon budget in subduction zones than previously estimated, particularly given its apparent efficiency over a wide range of P-T conditions. Furthermore, the reactivity of metafelsic lithologies such as orthogneiss to carbon-bearing fluids opens new perspectives for the evaluation of carbonation processes happening during continental subduction in collisional settings.

8. Conclusions

This work provides a structural, microstructural and geochemical overview of carbonate metasomatism in lawsonite-eclogite facies rocks from Alpine Corsica. Reactive fluid flow along major lithospheric lithological interfaces is evidenced by pervasive metasomatism and carbonation accompanied by multiple veining events. Our tectonostratigraphic and petrological study of carbonated metasomatic rocks facilitates inferences regarding the nature of the protolith rock, and provides tools to identify HP carbonation processes in other metamorphic terranes. Carbonate metasomatism is characterized by field evidence for fluid overpressure, including hydraulic breccias and crack-seal veining, and by reaction rinds between disparate lithologies. In most of the cases, the resulting structural and microstructural relationships give corrosion-like textures, notably with heterogeneous consumption and segmentation of silicate-rich domains. Fluid-rock interactions are recorded by microstructures (e.g. atoll-like minerals or embayed crystal rims), mineral zoning, and isotopic changes. Geochemical and isotopic data make us propose that the final fluid composition results from successive equilibration during reactive fluid flow. We propose that deeper fluids produced by major dehydration reactions can percolate parallel to the slab and chemically evolve by reactive flow (Fig. 12a). Importantly, we demonstrate that a large set of rock composition is reactive with COH fluids, ranging from ultramafic to metafelsic.
