running title: Cataract in Mauritania

Abstract

Background: Congenital cataract is the most frequent cause of childhood blindness. To date, more than 40 loci associated with cataract have been identified, including at least 26 genes on different chromosomes associated with inherited cataract. Here, we describe nine generations of a Mauritanian consanguineous family affected with congenital cataract. This study aimed to identify the genetic mutation in this Mauritanian family.

Methods: A detailed nine-generation autosomal dominant Mauritanian cataract family history and clinical data of the family members were recorded. A total of 14 family members, including 10 affected and 4 unaffected individuals were recruited. Targeted next-generation sequencing was performed to determine the disease-causing mutation. Sanger sequencing was used to confirm the results.

Results: A novel heterozygous missense mutation, c.166A>C (p.Thr56Pro), in *GJA8* was identified. This mutation co-segregated with all affected individuals and was not observed in the unaffected family members. The prediction of secondary structure from the protein sequence showed that the structure of the mutant protein was different with that wild-type *GJA8*.

Conclusions: We describe for the first time a missense mutation, c.166A>C in *GJA8*, which is associated with autosomal dominant congenital cataract in a Mauritanian family.

Introduction:

Cataract is commonly considered as an age related condition. This pathology may also be secondary to various after birth events or inborn[1-2]. Blindness from congenital cataract is indeed estimated to affect about 1-15 per 10,000 children in the developing world as the disease goes often undetected in early childhood resulting in most cases in permanent visual loss[3-4]. Hereditary congenital cataracts account for at least a third of all congenital cataract forms with the autosomal dominant being the most common familial form. They can also be transmitted as autosomal recessive or X-linked[4].

Of the thirty four genetic loci to which congenial cataracts, isolated or primary, have been mapped, a quarter of the known mutant genes are gap junction channel protein (connexins) encoding genes. Two of these genes code for α -connexins Cx46 (GJA3) and Cx50 (GJA8) which are the most abundant proteins in lens fiber cells and essential, respectively, in the lens transparency and development [5].

Although about 50% of blindness in African populations is resulting from cataract, studies on the etiologies of this often avoidable disorder are very limited. Besides, there is no data, to our knowledge, on the genes implicated in hereditary cataract in these populations.

Here, we described the segregation profile of a congenital nuclear cataract in a nine generation Mauritanian family living in an isolated village located in the south of Mauritania. Using next-generation sequencing of whole exome, we also investigated the underlying genetic defect and analyzed the potential structural organization of the mutant region.

Materials and methods

This Mauritanian family living in the village of Dali Gumba, in the Hodh region of southern Mauritania has been affected, over nine generations, by a blindness which develops in early years following a congenital cataract. A team of eye specialists from the CNH (Centre National Hospitalier) and biologists from the University of Sciences technologies and medicine has clinically examined and interviewed the members of the living family members. A pedigree and family medical history were recorded. Ophthalmological assessment including slit lamp was carried out for all family members. Fourteen individuals (10 patients and 4 unaffected subjects) were recruited for molecular investigation (figure 1a).

Targeted next-generation sequencing

DNA extraction, from peripheral blood collected in EDTA tubes, was carried out using QIAampDNA Blood Midi Kit (Qiagen, Hilden, Germany). Next-generation sequencing (NGS) was selectively conducted on the index case (figure 1a), using a custom-designed in-solution capture array targeting a panel of 116 cataract underlying genes. Details of the relevant genes are provided in **Appendix1**. Library preparation, qualification and NGS on the HiSeq2000 platform (Illumina, Inc., San Diego, CA) were performed as described previously [6]. The patient DNA, along other DNA samples, was multiplexed then randomly fragmented, ligated and amplified via ligation-mediated polymerase chain reaction (LM-PCR) [7]. After purification and hybridization, a quantitative PCR was then performed on LM-PCR products to assess the level of enrichment.

Bioinformatic analyses

Sequence reads alignment to the reference human genome 19 (hg19) with UCSC and nucleotide variation annotations were performed using single nucleotide polymorphism (SNP) databases, including HapMap project (<http://hapmap.ncbi.nlm.nih.gov/>), 1000 Genome Project (<http://www.1000genomes.org/>), Exome Variant Server (EVS, <http://evs.gs.washington.edu/EVS/>), and Exome Aggregation Consortium (EXAC, <http://exac.broadinstitute.org/>). In the Pathogenicity evaluation, amino acid change was considered as potentially disease causing if predicted by at least one of the programs (PolyPhen2, <http://genetics.bwh.harvard.edu/pph2/>), Sorting Intolerant From Tolerant (SIFT, <http://sift.jcvi.org/>) and Mutation Taster (<http://www.mutationtaster.org/>). (**Appendix2**) Amino acid conservation across species was studied with UCSC Genome Browser (<https://genome.ucsc.edu/>). (figure2). The conformational change induced by the DNA variation on the mutant protein was analyzed and compared to wild-type protein structure using CFSSP server (<http://www.biogem.org/tool/chou-fasman/>).

Sanger sequencing

The protein variant identification, following NGS, was confirmed in the index proband and thirteen other affected family members by Sanger sequencing (ref) using (human GJA8 reference sequence NM_005267.4, Forward: 5'- GCTCTTGCCTTCTCCCTCAT -3' and

Reverse: 5'- TGGCTTTCTGGATGGAGGAG-3'). The primers were designed using Primer3 (<http://bioinfo.ut.ee/primer3-0.4.0/>).

Approval to this study was given by the ethics committee of the University of Sciences, Technologies and Medicine, Nouakchott, Mauritania. The purpose of the study was explained to the participants and their informed and signed consent was obtained. For children, the parents approval was obtained.

Results

Clinical exploration

Inborn cloudiness of the eye natural lens was reported in all the interviewed patients. Following clinical examination, nuclear congenital bilateral cataract was confirmed in all suspected cases from both genders. Initial signs of interference with the vision were reported to be in the first two years of life. The disease progression varied slightly among patients. Preliminary examination did not reveal association with any common ocular anomalies or systemic condition. Cataract was observed in each generation and all affected individuals had at least one parent who carries the disease. These characteristics were consistent with an autosomal dominant inheritance.

Genetic screening

Next generation sequencing performed on the proband's DNA (Fig 1.a, *) and selectively targeting the coding exons of 116 congenital cataract associated genes showed, after filtration and validation, a pathogenic DNA missense variation, A>C at position 166 (c.166 A>C) in the Cx50 α -connexin gene (*GJA8*). (**Appendix1**).

This mutation, not reported before, resulted in the substitution of an evolutionarily highly conserved threonine at position 56 by a proline (p. T56P) (figure 1.c). This change was not observed in any of DNA samples from 15 individuals affected by other ocular pathologies and sequenced along the proband's DNA using the same NGS approach.

Sanger sequencing of the exon 2 of *GJA8* in the fourteen affected family members, including the proband, showed the same A>C mutation, at position 166 from the translation start site (figure 1.b). This co-segregation with the disease was found only in the cataract patients as none of the unaffected family members or the healthy controls showed this mutation.

Bioinformatics analysis

Using the wild type Cx-50 protein as template, the predicted three-dimensional structure impacted by the amino acid point mutation p.T56P showed a localized alteration, with a score of 1.00 using CFSSP, in the first extra membrane loop which consisted of the disruption of the wild-type sheet and its replacement, in the mutant protein, by a turn then coil (figure 2). This conformational change was assessed functionally as probably damaging with a score of 1.0 by SIFT and PolyPhen-2, respectively.

Discussion

Although blindness resulting from cataract is a primary health issue, data on the etiologies of this disease remained very limited in developing countries. In this study, we reported a bilateral nuclear cataract present at birth in a nine generation family living in a remote village of Southern Mauritania. The age of onset varied but in most patients, the vision impairment was noticed within the two first years with a progressive evolution. Surgery did not confer a visual benefit more likely due to the relatively advanced age, mostly above 6 years, of the patients at presentation. The timing of extraction in congenital cataract is indeed critical in ensuring visual rehabilitation as the ideal recommended age of its removal is about ten weeks to one year at the latest if the lens opacification is bilateral (8). These poor outcomes have greatly affected the trust of the family rulers in the medical benefit of the operation which resulted in that nearly all cataract-affected children became blind or greatly visually impaired.

Although the age at onset does not necessarily indicate the etiology, the presence of this cataract at birth and in several family members was evocative of an inherited cause. Besides, physical examination and personal medical history of patients did not reveal any underlying defined metabolic or infectious disorder. As in most inherited cataracts, the medical pedigree of the cataract phenotype in this family was consistent with an autosomal dominant pattern (9).

About 10 to 25 % of all cataracts are inherited and most of the genetically categorized congenital forms of this disorder were associated with known candidate genes (10-11). However, as no data were available on the specific implication of these cataract-related genes in any African or Arab population, we opted for a comprehensive NGS screening approach

using a large panel of 116 cataract underlying genes (6-12). This sequencing, confirmed by direct Sanger sequencing, showed a new missense variation at position 166 (c.166 A>C) in *GJA8* gene, on chromosome 1, which resulted, at protein level, in a p.T56P substitution in Cx50 α -connexin, a well known gap junction channel forming protein (13). This change was not observed in non affected family members or the healthy controls which supported the potential disease contributing effect of this mutation. This likely effect was also consistent with the position-specific independent count (PSIC) score of 1.000, as “probably damaging”, produced by PolyPhen-2, a well approved pathogenicity predicting software (**Appendix 2**). The effect of the substitution on the protein function was also signified using the CFSSP server (figure 2).

Different functional studies on expressed *GJA3* and *GJA8* mutant proteins have shown abnormalities likely to affect intercellular communication through channel alteration or cellular trafficking impairment resulting in the reduction of the number of efficient gap junction channels within the plasma membrane. Thus, in mouse lines, targeted deletions of Cx50 protein have been linked to inheritance of cataract through their effect on lens size and onset of disease phenotype (14). Data from transgenic mice also showed that alteration of the level of Cx50 production could result in lens opacification (15). Expressed human connexin mutants associated with congenital cataract have too showed biochemical and cellular aberration ranging from substantial reduction in gap junction plaques, generation of non-functional intercellular channels and formation of hemichannels with altered gating or charge selectivity properties (16-17).

In human families, more than forty missense Cx50 mutations, all transmitted in autosomal dominant mode, have so far been linked to congenital cataract on the basis of their disease segregation pattern and clinical appearance (table 1). The protein tertiary structure of Connexin 50, like other connexin family members, showed, besides the four highly ordered transmembrane segments TM1-TM4, the C and N cytoplasmic termini, three loops (two extra-cellular: EL1 - EL2 and one cytoplasmic: CL) (18). Nearly 50 % of all cataract related mutations have been mapped to E1 and E2 loops which, by several analysis, were found to be structurally fundamental for gap junction generation (19). Although we did not perform a protein stability or cell localization testing on the mutant protein found in this family, the positions of four mutations with respect to the membrane topology of the wild type C50 connexin showed that the replacement (p. T56P) concerned a highly conserved amino acid. This mutation, in loop E1, is also positioned in a site where numerous other congenital cataract

linked mutations have been identified (Table1). For instance, Cx50-S50P mutation (figure 1.c), close to our mutation T56P and also involving the introduction of a proline amino acid has been shown to affect lens physiopathology (21). The site of p.T56P substitution may therefore be determinant in the physiological contribution of connexin Cx50 and its integrity could affect the lens normal survival. In that respect, the conformational disruption predicted here i.e. the replacement of a β sheet in the wild type Cx50 connexin by the turn then coil in the mutant protein, is reasonable giving the known distinctive rigidity of the proline's side chain. Proline is indeed the only proteogenic amino acid with a constrained ϕ angle (approximately at -65°) due to the covalent locking of the nitrogen atom in the side chain five-membered ring. As a result of this angular restriction, interference of proline amino acid with the regular protein neighboring secondary structure (α helix or β sheet) is well documented (22).

As highlighted above, cataract phenotypes have been linked to several candidate genes. Although the mutations were largely in the same gene (*GJA8*), their respective occurrence appeared to reflect a population related distribution as most of these variants were reported in population of different origin (table1). A similar population allocation pattern has been reported for another heterogeneous monogenic disease i.e. beta thalassemia. This inherited blood disorder is indeed often caused, in a defined group, by a very limited number of β -gene mutations. For instance, in North African populations, nonsense mutation such as codon 39 (A > T) and splice junction IVSI-1 were the most common cause of β thal cases (23). In sub-Saharan African populations, Substitution (A > G) at position -29 in the Tata box and IVS2-849 have been reported respectively in β^+ and β^0 U.S. black African patients (24). Giving the absence of any data on inherited cataract in African populations, we could not relate our mutation to an existing cataract variant in these populations. However, the affected family belongs to the Moors (Maures) which is the predominant ethnic group of the Mauritanian population. This group of berber-arab origin ethnically self-identifies with the neighboring North Africa populations (25). Although no cataract associated mutation has so far been reported in this region and the specific ethnic occurrence of 166 (c.166 A > C) remains to be ascertained, this finding may be relevant in the population distribution analysis of future cataract related gene mutations in these populations.

Looking at the broader contribution of variant c.166 A > C, this new mutation expands the spectrum of cataract associated DNA variants (table1). Besides, it was found in a remotely located family. Characterization of biomarkers in ethnically or geographically restricted

groups has indeed been reported to be more pertinent, than in general population studies, in understanding the heritability of population common genetic traits and diseases associated variants. This mutation, giving its protein location and specific ethnic occurrence may therefore contribute in assessing the physiopathology of inherited cataract.

Conclusion

In this study, we identified a family new mutation (c.166 A>C) in GJA8 segregating with a nuclear congenital cataract. Giving that no other associated mutation was found in the proband's DNA using the powerful screening technique of NGS and its segregation with the phenotype, this mutation might be useful as a predicting marker of the disease onset before the clinical manifestation of the lens opacification.
