Bioturbation
Soil physical properties
Galleries
Saturated hydraulic conductivity

In the tropics, termites are key litter decomposers and soil bioturbators. Termite foraging activity involves the production of sheetings and galleries that influence the physical, chemical and hydraulic properties of soils. The functional impacts of these biogenic structures and biopores have been acknowledged for a long time in soils dominated by 1:1 minerals. Less is known, however, on their functional impacts in soils dominated by 2:1 minerals, such as vertisol which represent 22% of the land surface in India. Therefore, an experiment was carried out in a vertisol in southern India where elephant (*Elephas maximus*) dung pats (ED) and *Lantana camara* twigs (LT) were applied on the ground and protected (+) or not (−) from termite activity. Termite activity was only measured below ED −, showing a clear preference for organic matter derived from elephant dung. Soil sheetings had similar properties to the surrounding topsoil, with the exception of their C content that was reduced. This result raised the question of the origin of the soil used by termites for covering ED. ED − was also associated with the presence of effective macropores up to 5 cm depth and a significant increase in water hydraulic conductivity (12-fold). However, the utilization of the coefficient of linear extensibility showed that these galleries were unstable and most likely short-lived. In conclusion, this study confirmed that the structure of soils dominated by 2:1 minerals is mainly controlled by physical processes (i.e., the shrinking and swelling of soils). This study also stresses the need to better understand the dynamic of termite galleries in soil and to quantify the origin and fate of organic matter in soil sheetings.

1. Introduction

Fungus-growing termites are amongst the most important litter decomposers and soil bioturbators in arid and semi-arid environments (Bignell and Eggleton, 2000; Bottinelli et al., 2015). As “intended engineers” (*sensu* Jouquet et al., 2006), they build important and complex nest structures (i.e., mounds or termitaria) that protect colonies from predators and maintain a stable environment for the colony and their symbiotic fungus to grow (Lüscher, 1961). The functional impact of these mounds has been largely recognized (see Holt and Lepage, 2000; Jouquet et al., 2016; Khan et al., 2018 for reviews), especially in Africa where they constitute biodiversity and nutrient hot spots that increase the robustness of ecosystems (Bonachela et al., 2015).

Termites also influence ecosystem functioning through the production of subterranean galleries and sheetings to protect themselves from light, desiccation and predators while they forage (MacKay et al., 1985; Harit et al., 2017a,b; Fernandes et al., 2018). From studies carried out in sandy soils or in soils dominated by 1:1 minerals (e.g., sandy loams and Acrisol), it is usually considered that galleries constitute preferential flow paths and then increase water infiltration, reduce crust formation, water runoff and soil erosion in arid and sub-arid ecosystems (e.g., Eldridge and Pickard, 1994; Mando et al., 1996, 1999; Mando, 1997; Sarr et al., 2005; Mettrop et al., 2013; Léonard and Rajot, 2001; Léonard et al., 2004; Colloff et al., 2010; Kaiser et al., 2017). Although less known, a recent review suggests that soil sheetings are always enriched in clay in comparison with the surrounding soil but that their

E-mail address: sougueh.cheik@ird.fr (S. Cheik).

C content varies depending on the C content of the putative parent soil (Harit et al., 2017b). Moreover, an experiment carried out in a humid tropical environment showed that the low stability of soil sheetings to water increases soil detachment, the sealing of soil surface and water runoff (Jouquet et al., 2012).

Conversely, the impact of termites on water dynamic is unknown in soils dominated by 2:1 minerals. In India, Vertisol soils occupy a large surface with 70.3 million ha, constituting 22% of the total geographical area (Mandal et al. 2013). These soils are subject to shrinkage after wetting and drying cycles, leading to the formation of physcogenic aggregates (*sensu* Pulleman and Marinissen, 2004; Jouquet et al., 2009) and cracks which serve as preferential pathways for rainwater. In these soils, biogenic structures are considered unstable and the ecological impact of soil fauna on soil dynamics to be non-significant or of low importance (e.g. Oades, 1993; Blanchart et al., 2004), although the question has never been addressed with termites, and especially in India. Therefore, the objective of this study was to determine how termite foraging activity impacts soil aggregation and water infiltration (i.e., through the production of sheeting and galleries) in Vertisol soils in India. Our hypothesis was that termite galleries and sheetings do not resist water, due to the swelling behavior of soils, and therefore that the influence of termite foraging activity on soil aggregate stability and water infiltration is of minor importance.

2. Materials and methods

2.1. Study site

This study was carried out in a private land situated within a dry zone of the Nilgiri Biosphere Reserve of southern India (11°31'50.84"N and 76°38' 37.11"E). With about 600 mm year⁻¹ on average, the vegetation here is described as tropical dry-thorn forest. With approx. 30% of clay dominated by 2:1 clays and 4.5% of C in the 0–20 cm soil layer, the soil is described as Vertisol in the US Soil Taxonomy (USDA) and FAO classifications (Soil Survey Staff, 2014). In this environment, soil bioturbation mainly results from the activity of fungus-growing termites, mainly *Odontotermes obesus* and *O. redemanni*.

2.2. Experimental setup

The experiment was carried out from March to June 2016 during the dry season when the land had few herbaceous plants and low grass cover, with the exception of some patches of the invasive, woody shrub *Lantana camara*. The experiment consisted in the application of elephant (*Elephas maximus*) dung pads (~250 g) and *Lantana camara* twigs and leaves (~400 g) on the ground. Elephant dung was chosen because it is an attractive, although sporadic, resource for termites in the field (Chaudhary Ekta, pers. obs.). *Lantana camara* is an invasive species native to the Americas (Patel, 2011; Ramaswami and Sukumar, 2014) and constitutes an abundant but unpalatable resource of organic matter to soil detritivores because of the allelopathic chemicals it contains (Verma and Verma, 2006; Verma et al., 2009). Elephant dung pads (ED) and *Lantana camara* twigs (LT) were enclosed in 100 µm mesh size nets (ED+, LT+) or not (ED–, LT–) and their impact on termite activity was compared to a control (CTRL) without organic amendment. The number of replicates (n) equaled to 5 for ED+, LT+ and LT– but we used n = 10 in the case of the control and ED–. 5 replicates were used for measuring water hydraulic conductivity and soil physical and chemical properties for all the treatments and the 5 additional replicates for ED– and CTRL were used for measuring soil macroporosity after the application of methylene blue water (see below).

2.3. Soil sheeting properties

At the end of the experiment, soil sheeting was found on elephant dung. Sheetings were sampled and their properties analyzed and

compared to the surrounding top-soil (0–2 cm depth, > 1 m distance from the dung patch) (n = 5). Soil pH and conductivity were determined in 1:5 soil: water suspension and the C content was determined with a SHIMADZU TOC V_{CSH} analyzer (model SSM-5000A). The particle-size distribution was assessed after destruction of soil organic matter and dispersion with hydrogen peroxide and sodium hexametaphosphate. Particles were differentiated into clay (< 2 µm), silts (2–50 µm) and sand (50–2000 µm) after sieving and sedimentation. Soil aggregate stability was measured after immersion of 5 g of > 2 mm soil aggregates in 15 ml distilled water for 5 min. The fraction of soil > 200 µm was used to measure the percentage of water stable aggregates, after correction to their sand content.

2.4. Water infiltration and diffusion

Soil hydraulic conductivity was measured with the Beerkan method (Haverkamp et al., 1994; Braud et al., 2005; Lassabatère et al., 2006) and using a cylinder in plastic (in polyvinyl chloride or PVC) having an inner diameter of 11 cm. The cylinder was positioned at the soil surface and inserted to a depth of about 1 cm. A fixed volume of water (100 ml, corresponding to a water depth of about 1 cm) was poured into the cylinder and the time needed for the water to infiltrate was measured. The procedure was repeated between 7 and 10 times for it to reach a steady state of infiltration. The undisturbed soil cores were used to determine the soil bulk density, ρ (g cm⁻³) and the initial volumetric water content, θ_i (m³ cm⁻³), was measured after sampling the surrounding top-soil environment (0–5 cm depth). Results were analyzed with the original BEST algorithm (Lassabatère et al., 2006) in order to calculate the saturated hydraulic conductivity (K_{sat}).

The presence of effective macropores was measured for ED and CTRL treatments using methylene blue as a dye tracer (Capowiez et al., 2009). As for the measure of K_{sat} , cylinders were installed at the soil surface and poured with 3 cm of water (=300 ml) containing methylene blue (concentration = 0.01 M). After 12 h, the soil below the PVC rings was excavated with a spade in order to prepare successive horizontal planes at 0, 0.5, 1, 2, 3, 4 and 5 cm depth. The surface was then photographed. The pictures were analyzed and the surface of each visible stained macropore was measured using Image J software.

2.5. Below-ground soil physical and chemical properties

The hydrostructural stability (Schäffer et al., 2008) of soil porosity was assessed from the measure of the coefficient of linear extensibility (COLE) defined by Grossman et al. (1968). Undisturbed soil samples were collected from the surface soil layer (0–5 cm) using cylinders (5.7 cm diam × 5 cm high) at each sampling location after measuring soil water infiltration rate, as described in Section 2.3. Soil samples were dried at 40 °C for 48 h and then partially immersed with water until saturation by capillarity. The COLE was computed as follows:

$$COLE = (L_0 - L_{105}) / L_{105}$$

where L_0 and L_{105} are the height of soil cores at saturation and after oven drying at 105 °C. Soils were also sampled at 1–3 cm depth and analyzed for total C and particle size distribution contents as described above. Furthermore, to estimate root biomass, each sample was placed in a beaker and soaked in water for at least 30 min, so that soil aggregates can be easily broken down. Afterwards, the soil samples were washed through a 200 µm sieve. Roots were rinsed to remove any excess of soil and weighted after drying at 60 °C for 48 h.

2.6. Statistical analyses

All statistical calculations were carried out using R and RStudio (version i386 3.2.5). The number of replicates was determined using the power.anova.test function for a power of the test equal to 0.8. Data were balanced (equal number of observations for each factor) and the

normal distribution of residues was tested using the Shapiro-Wilk test. One-way ANOVA was used to analyze the soil chemical and physical properties with treatments as independent variable. LSD tests were then performed to assess differences between means. T-tests were used for comparing (i) termite sheeting properties from the properties of the topsoil and (ii) the surface dyed by methylene blue for ED– and CTRL treatments for each soil depths. Multiple linear regressions were used to assess the influence of soil physical and chemical properties (C, sand, silt or clay contents, soil bulk density, root biomass, COLE) on *Ksat*. Finally, an analysis of covariance (ANCOVA) was used to compare the effect of the treatments (LT– and ED– vs. CTRL, LT+ and ED+), as covariate, on the linear relationship between COLE and *Ksat*. Differences among treatments were declared significant at the $P < 0.05$ probability level.

3. Results

3.1. Impact of termite activity on soil physical and chemical properties

After three months, termite activity was recorded only in ED–. Termites were identified as *Odontotermes obsesus* or *O. redemanni*. Apart from termites, no other soil macrofauna was found. Since termites were only measured in ED–, soil sheetings could only be collected for this treatment and their properties compared to the surrounding soil. Soil sheetings had the same physical and chemical properties as the topsoil (Table 1), with the exception of the soil C content that was significantly lower in termite sheetings than in the control ($P < 0.05$).

The influence of the different treatments on below-ground soil properties is shown in Table 2. Soil physical and chemical properties were not influenced by the different treatments ($P > 0.05$ in all cases), with the exception of *Ksat* which was significantly higher in ED– in comparison with CTRL, LT+ and ED+ ($P < 0.05$, Fig. 1). LT– had an intermediate *Ksat* value, not significantly different from ED– and CTRL, LT+ and ED+ ($P > 0.05$ in all cases).

3.2. Abiotic variables explaining the evolution of *Ksat* in soil

Stepwise regression shows that *Ksat* was linearly related to COLE and in a smaller extent to the silt content of soils (Table 2, $Ksat = 0.03-0.62 \text{ silt } (\%) + 1.67 \text{ COLE}$, $R^2 = 0.37$, $p = 0.006$). Results of the ANCOVA testing the influence of COLE on *Ksat* with soil macrofauna activity (associated to ED– and LT–) as covariate showed a significant difference in slope across groups ($F_{1,21} = 13.27$, $P = 0.001$). No relationship was found between *Ksat* and COLE in CTRL and below substrates that were protected from soil macrofauna activity (ED+ and LT+) ($P = 0.550$), while Fig. 2 shows a positive linear relationship below non-protected substrates (ED– and LT–) ($Ksat = 2.068 \times COLE - 0.082$, $R^2 = 0.56$, $P = 0.012$).

3.3. Diffusion of methylene blue water in soil

The surface of soil dyed in blue decreased with soil depth (Fig. 3). No significant differences between CTRL and ED– could be measured up to 3 cm ($P > 0.05$ in all cases). Methylene blue could not be measured after 3 cm depth for CTRL while it reached 5 cm depth in ED– with ~3.8% of the soil dyed in blue at 5 cm depth ($P < 0.05$ at both 4

Table 2

Results of the ANOVA testing the influence of the treatments on soil physical and chemical below-ground properties: sand, silt and clay contents, C content, Soil bulk density, root biomass, *Ksat* and COLE. Significant results at 0.05 are highlighted in bold characters.

	<i>F</i>	<i>P</i> -value
Sand	$F_{4,20} = 0.216$	0.927
Silt	$F_{4,20} = 0.991$	0.435

and 5 cm depth).

4. Discussion

4.1. Influence of litter quality on termite activity

The opportunistic consumption of mammalian dung by termites has been described long ago (e.g., Ferrar and Watson, 1970; Freymann et al., 2008). In our case, elephant dung piles were rapidly detected by termites and their consumption was associated to the presence of soil sheetings. Although no sheeting was found on *Lantana camara*, intermediate *Ksat* values were measured in LT– in comparison with ED– and CTRL or LT+. Therefore, these results suggest that LT– was associated with the presence of macropores in soils, even if they were not consumed by termites. No other soil decomposer was observed in our study site but our experiment did not allow rejecting the hypothesis that LT– also favored the activity of other soil burrowers (e.g., diplopods, ants) during the 3 months of the experiment. However, we consider that this hypothesis is unlikely because of the dryness of the soil during the dry season and because no ants or diplopods were measured in ED– and LT– at the end of the experiment. Therefore, we assume that termites were initially attracted by the availability of *Lantana camara* on the ground and then produced soil galleries reaching these

Fig. 3. Surface of the soil dyed with methylene blue water (in %) for different soil depths (0, 0.5, 1, 2, 3, 4 and 5 cm) and for the control soil (in white) and below ED- (in black), $n = 5$. “ns” for non significant and * for $P < 0.05$. (For interpretation of the references to colour in this figure legend, the reader is referred to the web version of this article.)

substrates. However, the production of galleries remained limited because *Lantana camara* was not consumed by termites, mainly because of its repellent properties (Verma et al., 2009; Ding and Hu, 2010; Yuan and Hu, 2012). Consequently, it can be concluded from this experiment that elephant dung is a sporadic, unpredictable but effective resource for termites and might be preferred to *Lantana camara*, which is an abundant but unattractive resource, if the aim is to stimulate termite foraging activity in the field.

4.2. Bioturbation by termites and soil sheeting properties

Termite foraging activity is associated with the production of soil sheetings. Our study shows that these biogenic structures had similar properties than the surrounding topsoil, with the exception of their C content. The similar particle size distribution between sheetings and their surrounding topsoil can be explained by the relatively homogeneous organization of the upper half meter of Vertisols (Sehgal, 2012), with the exception of the soil C content that can reach $> 5\%$ in the first few cm and can drop to a few % in deeper soil layers. For instance, 20 km away from our study site, Jouquet et al. (2017) found a C content of 3.5% in the 0–5 cm soil layer of a Vertisol and 1.22% in their 30–70 cm soil layer. In our study, the lower C content in sheeting suggests that they were not made of soil collected in the topsoil but rather below 30 cm depth. Although more research is clearly needed to confirm our results in other soil pedological contexts, we consider that

termite foraging activity is likely to be associated with a modification of C dynamics in soil, with the translocation of potentially old organic matter from deep soil layers to the surface. This hypothesis does not confirm the results of Diouf et al. (2006) and Villenave et al. (2009) who concluded that sheetings made by fungus-growing termites are produced by translocating soil from the superficial strata (0–3 cm) to the surface in African savannas. However, they are in line with the results of Harit et al. (2017b) who showed that sheetings are enriched in C when the surrounding topsoil has a low C concentration ($< 1\%$) while they are impoverished in C when the surrounding topsoil has C content $> 1\%$. Finally, despite lower C content, soil sheetings were as stable as topsoil aggregates, thus confirming the limited impact of soil macrofauna on soil aggregation in vertisol (Oades, 1993; Blanchart et al., 2004).

4.3. Impact of termites on soil porosity and water dynamic

In structured soils, macropores can act as preferential flow paths (Beven and Germann, 1982) when they are disconnected from other pores. In our case, termite preference for elephant dung was associated with the production of belowground galleries that increased K_{sat} . This finding confirms previous studies carried out in West Africa that showed a positive impact of termite foraging activity on soil water infiltration (Mando et al., 1996, 1999; Léonard et al., 2004), although other studies concluded about a non-significant or negative impact (Mando et al., 1999; Mettrop et al., 2013). In our experiment, K_{sat} was increased by approximately 12-fold in comparison with the control soil (0.049 vs. 0.004 mm s^{-1}). This result is in line with the findings of Mando and van Rheenen (1998) (10.5-fold) or Kaiser et al. (2017) (1.5–9.28-fold), although termite foraging activity is usually only increased by only 1.5–3-fold (Elkins et al., 1986; Mando et al., 1996, 1999; Léonard and Rajot, 2001).

In Sahel, Léonard and Rajot (2001) found that galleries made by *Odontotermes* sp. are mainly superficial and horizontal within the first cm of soil. In our study, results from the methylene blue method did not allow us to show a beneficial impact of termites on the first cm of soil but rather suggest a presence of galleries beyond 3 cm of depth. Consequently, this suggests that termites preferred building galleries in deeper soil layers than in Sahelian environment and/or that superficial galleries are unstable and rapidly degraded while galleries built in depth are less susceptible to crack formation. Indeed, higher COLE was measured with the presence of termite activity, whereas clay content was similar. This indicated that termite burrows were less stable than other types of pores during soil drying, confirming therefore our

hypothesis that few or no burrows can be found close to the surface because of their low hydrostructural stability.

5. Conclusion

This study confirms the general assumption that soil fauna has a limited impact on the dynamic of soil structure in soils dominated by 2:1 minerals. Soil sheetings were very similar in their properties to the surrounding topsoil, with the exception of the C content. However, their lower C content raised the question of the origin of the soil used by termites for building their sheetings. More research is also clearly needed to determine the dynamics of the C contained in soil sheetings, especially if it comes from a deeper and older SOM pool. Termite foraging activity is also associated with the production of galleries which temporarily increase soil water hydraulic conductivity. However, the results of this study raise the question of the resistance of these biopores to shrinking-swelling cycles, which are characteristic of soils dominated by 2:1 minerals. We suggest that the lifetime and durability of these galleries represent some important topics that require more research to develop a complete understanding of the influence of termites on the dynamic of soil structure.

Acknowledgments

We would like to thank Prof. S. Subramanian and J. Riotte for their supports and for allowing us to have access to facilities from IISc. We also thank the Editor and the two anonymous reviewers for their useful suggestions on the draft script. Raman Sukumar was a JC Bose National Fellow during the tenure of the study.
