ABSTRACT

Absorption lines in front of distant quasars are quite rare in the millimeter domain. They can, however, bring very useful and complementary information to emission lines. We report here the detection with NOEMA of CO(1-0) and CN(1-0) lines in absorption, and the confirmation of CO emission in the quasar/galaxy pair Q0248+430/G0248+430. The system G0248+430 corresponds to two merging galaxies (a Seyfert and a LINER) at $z=0.0519$ with a tidal tail just on the line of sight to the background quasar Q0248+430 at $z = 1.313$. Optical (CaII, NaI), H I-21cm, and OH-1667 MHz absorption lines associated with the tidal tail of the foreground system have previously been detected toward the quasar, while four CO lines at different rotation J levels have been detected in emission from the foreground galaxies. New H I 21cm line observations with the upgraded GMRT array are also presented. We discuss the molecular content of the merging galaxies, and the physical conditions in the absorbing interstellar medium of the tidal tail.

Key words. Galaxies: active — Galaxies: ISM — Galaxies: nuclei — Galaxies: quasars: absorption lines — Galaxies: quasars: general

1. Introduction

Most of our knowledge of molecular gas in galaxies at high or low redshift have been obtained through CO emission line studies. However, absorption lines can bring new and complementary information. In contrast to emission, absorption lines remain observable at practically any distance, with the sensitivity only determined by the strength of the background source (e.g., Combes 2008). Given a strong enough continuum source, (≥ 50 mJy), millimeter-wave absorption lines can be used to obtain information about molecular gas and star formation in “normal” galaxies. While emission lines are sensitive to dense and warm molecular gas, absorption lines may also arise from low-excitation and diffuse gas, which is more prevalent in normal galaxies (e.g., Wiklind & Combes 1995, 1996, 1997; Menten et al. 2008; Henkel et al. 2009; Muller et al. 2014).

Once a galaxy has been detected in the strongest CO absorption lines, deeper studies in other molecular lines allow characterization of the physical and chemical conditions in the absorbing gas (e.g., Henkel et al. 2005; Bottinelli et al. 2009; Muller et al. 2014, 2016; Riquelme et al. 2018). The relative strengths of species like HC₃N, where the excitation is dominated by the cosmic microwave background (CMB), can be used to determine the CMB temperature (e.g., Henkel et al. 2009; Muller et al. 2013). Comparisons between the redshifts of different transitions (e.g., NH₃, CH₃OH, OH) can be used to test for cosmological variations in the fundamental constants (e.g., Uzan 2011; Kanekar 2011; Kanekar et al. 2012; Rahmani et al.

2012; Bagdonaitė et al. 2013).

In this paper we report the discovery of CO absorption at $z \sim 0.05$, in front of the quasar Q0248 at $z = 1.31$ (Kuehr 1977). The absorption comes from a foreground pair of galaxies called G0248 (Junkkarinen 1987), consisting of the two sources G1 and G2. A tidal tail connects, in projection, G2 with the background quasar. Optical absorption lines (CaII and NaI) have been detected at the G0248 redshift $z = 0.05194$, or very close (0.05146, at ~ 150 km s⁻¹) by Sargent & Steidel (1990) and Womble et al. (1990). They noted that the QSO and the galaxy nuclei are separated by $14.7'' = 14.7$ kpc at $z=0.05$, and the absorption is due to the tidal tail crossing the quasar (see Fig. 1).

Throughout this paper we use the Λ CDM cosmology with $\Omega_m=0.3$, $\Omega_\Lambda=0.7$, and $H_0=70$ km s⁻¹ Mpc⁻¹. At the redshift of the foreground galaxies, the distance scale is 1 kpc per arcsec.

2. Apparent quasar-galaxy merger association

The associated pair of galaxies G0248 is a violent starburst, according to its IRAS far-IR (FIR) flux density measurements, corresponding to $L_{\text{FIR}} = 4.3 \times 10^{11} L_\odot$, and a star formation rate (SFR) of 74 M_⊙/yr (see Table 1), and the G1 and G2 nuclei (separated by $3.5'' = 3.5$ kpc) both show nonthermal activity (Borgeest et al. 1991; Kollatschny et al. 1991). Indeed, G1 is a LINER and G2 a Seyfert 2, and based on their optical emission line excitation both are located in the AGN region of the Baldwin-Phillips-Terlevich (BPT) diagram (Baldwin et al. 1981), plotting [OIII]/H β as a function of [NII]/H α . We note that the above FIR luminosity is extrapolated between 1 and 500 μm , as in Table 1, while Gupta et al. (2018a) adopt the calibration formula from

[★] Based on observations carried out with NOEMA, the Northern Extended Millimeter Array – IRAM (Institute of Radioastronomy in Millimeter).

Sanders & Mirabel (1996) and find $L_{\text{FIR}} = 3.5 \times 10^{11} L_{\odot}$, which is in good agreement. The background quasar Q0248 is a well-studied radio source and has a variable, flat spectrum (Massaro et al. 2014). Its flux density at 100 GHz has been observed to be around 200 mJy. The variability of the quasar could be due in part to micro-lensing by stars in the tidal tail of G0248 (Borgeest & Schramm 1994). An OH megamaser has been detected from the starburst (Kazes et al. 1989; Darling & Giovanelli 2002). Kollatschny et al. (1991) determine the kinematics of the two merging galaxies, the LINER G1 and Seyfert G2; the former shows systematic rotation, but the latter does not. With respect to G2 ($z=0.0507$), a constant velocity of $\sim 100 \text{ km s}^{-1}$ is observed all across the tidal tail. Furthermore, from their spectra, they conclude that G1 is a spiral galaxy and G2 an elliptical. Downes et al. (1993) report the detection of CO(1-0) emission, with an integrated flux of 25 Jy km s^{-1} with the IRAM 30m telescope. With the NRAO 12m telescope, Walker et al. (1997) confirm this detection, and show a quite high CO(2-1) excitation, with a ratio of ~ 4 between the CO(2-1) and CO(1-0) integrated fluxes, taking into account a common full width at half maximum (FWHM) of 175 km s^{-1} . Observations of CO(3-2) with the JCMT (James Clerk Maxwell Telescope) by Leech et al. (2010) reveal a CO(3-2)/CO(1-0) flux ratio of ~ 6 . Papadopoulos et al. (2010) find a CO(6-5)/CO(1-0) flux ratio of 16, showing that the peak of the excitation is around $J=3-4$. Hwang & Chiou (2004) have mapped the galaxy pair in CO(1-0) at $2''$ resolution using the Berkeley Illinois Maryland Array (BIMA). They confirm the integrated flux of 25 Jy km s^{-1} found by Downes et al. (1993) showing little or no interferometer filtering (see our spectrum in Fig. 2). They also show H₁-21cm absorption detected with the Very Large Array (VLA, $1.8''$ beam) in front of the quasar, which remains unresolved in the 21cm continuum. The H₁ absorption is at the same velocity as the CaII and NaI lines. Gupta et al. (2006, 2018a) have detected the strongest line (at 1667 MHz rest frequency) of the OH 18cm transitions in absorption in front of the quasar with a total integrated optical depth of $0.08 \pm 0.01 \text{ km s}^{-1}$, showing that molecular gas exists in the tidal tail. For an excitation temperature of 10 K, the observed 1667 MHz OH optical depth corresponds to a column density of $N(\text{OH}) = 1.8 \times 10^{14} \text{ cm}^{-2}$; similar column densities ($10^{13-14} \text{ cm}^{-2}$) are observed in diffuse clouds, while typical values for giant molecular clouds (GMC) are $10^{15-16} \text{ cm}^{-2}$. The BIMA observations by Hwang & Chiou (2004) did not lead to any detected CO absorption in front of the quasar, but the data suffered from a low sensitivity ($N(\text{CO}) < 10^{16} \text{ cm}^{-2}$).

Assuming a spin temperature of $\sim 1000\text{K}$, Hwang & Chiou (2004) derive a column density of $N(\text{H}_1) = 5 \times 10^{20} \text{ cm}^{-2}$. However, this is based on a derived integrated optical depth at 21cm of $\int \tau_{21} dv = 0.26 \text{ km s}^{-1}$. Gupta et al. (2018a) reprocessed these archival VLA data, and found $\int \tau_{21} dv = 0.43 \pm 0.02 \text{ km s}^{-1}$. The column density of the H₁ gas in front of the quasar is large enough for the absorber to be classified as a damped Ly α system, provided the spin temperature is higher than 300 K and/or the covering factor is less than unity.

The calcium depletion on grains of the absorbing gas is high, indicating that the gas must come from a disk rather than from a halo. The column density of NaI is $6.3 \times 10^{13} \text{ cm}^{-2}$ (Womble et al. 1990), while the ratio $N(\text{CaII})/N(\text{NaI})=0.2-0.3$ is low, similar to or lower than the values ~ 1 of the Galactic disk. The high NaI suggests that the gas could come from outflowing gas from the starburst or the active nuclei in the tidal tail (Heckman et al. 2000). The absence of H₁ emission in the VLA observations (upper limit at 5σ of $2.3 \times 10^{22} \text{ cm}^{-2}$ over 30 km s^{-1}) is likely

due to the phase transformation of the atomic gas to molecular gas in the starburst, which now contains $M(\text{H}_2) = 1.6 \times 10^{10} M_{\odot}$, with a standard CO-to-H₂ conversion factor, $X(\text{CO}) = 2 \times 10^{20} \text{ cm}^{-2} / (\text{K km s}^{-1})$.

3. Observations and data analysis

3.1. IRAM observations

We have mapped G0248 at 109.605 GHz for a total of 13 hr (8 hr on source) allowing us to spatially resolve the CO(1-0) emission line in the foreground gas, and the continuum emissions from both the foreground merging system and the background quasar.

The phase center was $\text{RA}(2000) = 02\text{h } 51\text{m } 35.1\text{s}$, $\text{Dec}(2000) = 43^{\circ} 15' 14.0''$, corresponding to the barycenter of the quasar and the merging system (both are located at $\sim 6.5''$ from the phase center). The observations were made with nine antennas using the extended array A-configuration of the NOEMA interferometer (project W17CE, P.I.: Combes). The configuration provided a synthesized beam of $0.94 \times 0.67 \text{ arcsec}$ ($\text{PA}=60^{\circ}$). This allows us to resolve the two merging galaxies, which are separated by $3.5'' = 3.5 \text{ kpc}$. The field of view at half power is $47''$ at this frequency. The observations were carried out during five days (10, 16, 23, 25 February, and 2 March 2018) in very good weather conditions (seeing in the range $\sim 0.1-0.4 \text{ arcsec}$).

We employed the PolyFix correlator in Band 1 (3 mm), which provides $2 \times 8 \text{ GHz}$ of instantaneous dual-polarization bandwidth. The spectral resolution was 2 MHz (5.4 km s^{-1} at the redshifted CO(1-0) frequency). The bandwidth allowed us to observe the frequency range from 91.9 to 99.7 GHz in LSB (Lower SideBand), and 107.3 to 115.1 GHz in the USB (Upper SideBand). The data reduction was performed using the latest release of the GILDAS package as of May 2018¹. The data were calibrated using the NOEMA standard pipeline adopting a natural weighting scheme to optimize both sensitivity and resolution. Flagging was required only on the February 10 data, and was minor. The rms noise is 0.3 mJy in 30 km s^{-1} channels for the line and $8 \mu\text{Jy}/\text{beam}$ for the continuum.

3.2. uGMRT observations

We used Band-5 (1000-1450 MHz) of the upgraded Giant Metrewave Radio Telescope (uGMRT) to observe the redshifted H₁ 21cm line toward the quasar. The observations took place on 29 June 2018. The GMRT Software Backend (GSB) was used to configure a baseband bandwidth of 4.17 MHz split into 512 spectral channels (resolution $\sim 1.8 \text{ km s}^{-1}$) centered at 1350.8 MHz . During the 7.5-hour observing run, 3C48 was observed for flux density scale and bandpass calibrations. The total on-source time was 6.6 hours. The data were edited, calibrated, and imaged using the Automated Radio Telescope Imaging Pipeline (ARTIP) that is being developed to perform the end-to-end processing of data from the uGMRT and MeerKAT absorption line surveys (Gupta et al. 2018b; Sharma et al. 2018).

The Stokes *I* radio continuum image made using the line-free frequency channels and using ROBUST=0.5 visibility weighting (based on Common Astronomy Software Applications, CASA) is shown in Fig. 1. The image has a synthesized beam of $2.49'' \times 2.22''$ and an rms noise level of $0.45 \text{ mJy beam}^{-1}$. The radio continuum emission associated with Q0248+430 and G1 is unresolved with a deconvolved size $< 0.2''$. The integrated flux

¹ <https://www.iram.fr/IRAMFR/GILDAS/>

Fig. 1. **Top:** uGMRT radio continuum (1.35 GHz) contours overlaid on the PS1 r -band image. The contour levels are 2.2×2^n mJy beam $^{-1}$ (where $n=-1,0,1,2,3,\dots$). The restoring beam of $2.49'' \times 2.22''$ with position angle -35.6° is shown in the bottom left corner. The strong source at the SE of G0248+430 is a foreground star. **Bottom:** The PS1 r -band image in contours, to better show the tidal tail, in front of the quasar.

densities are 1214 ± 1.3 and 23.7 ± 1.3 mJy, respectively. We extracted the Stokes I 21cm absorption spectra toward Q0248+430 and G1. The spectral rms noise level in the unsmoothed spectra is 1.2 mJy beam $^{-1}$. The spectrum of Q0248+403 is presented in Fig. 2. Ninety percent of the total 21cm optical depth is contained within 49 km s $^{-1}$ and the total integrated 21cm optical depth, $\int \tau dv = 0.53 \pm 0.02$ km s $^{-1}$. In the spectrum of G1 (not shown here), we detect a broad absorption feature ~ 100 km s $^{-1}$ in width centered at 1351.06 MHz. It corresponds to an integrated optical depth of 19 ± 1 km s $^{-1}$. However, in the different circular polarizations (L for left, R for right) and their cross-correlations, this feature is present only in LL and not in RR; therefore, we consider the feature to be an artifact. For G0248+430 we then use the RR spectrum smoothed to 30 km s $^{-1}$. Adopting 100 km s $^{-1}$ as the FWHM of a typical associated 21cm absorption line (Gupta et al. 2006), we estimate a 3σ 21cm integrated optical depth limit of 6 km s $^{-1}$.

4. Results

4.1. Implication of CO absorption

The CO(1-0) emission and possible absorption was mapped in the NOEMA field of view of 47 arcsec FWHM around the merging galaxies (G1 and G2 of Fig 1) with $0.94'' \times 0.67''$ resolution. Although the quasar and the tidal tail were only at an angular distance of $6.5''$ from the phase center, the sensitivity was not sufficient to detect molecular emission in the tidal tail.

Fig. 2. HI 21cm, OH (1667 MHz), CO(1-0), and CN(1-0) absorption spectra toward the quasar Q0248+430. The zero of the velocity scale ($z = 0.05151$) is centered at the peak of the low resolution HI 21cm absorption line (Gupta et al. 2018a). The vertical scale is flux normalized to the continuum.

While it was quite easy to detect the radio continuum of the quasar, at a level of 0.155 Jy (and the foreground absorption toward it) it was not possible to detect the two AGN nuclei in the continuum of G2 (Seyfert) or of G1 (LINER), the latter being detected at centimeter wavelength.

The quasar continuum source is unresolved. In the millimeter range, AGN continuum sources are in general restricted to a core smaller than a milliarcsec in size, contrary to the cm emission, extended due to steep spectrum radio lobes (e.g., de Zotti et al. 2010). This size corresponds to 1 pc at the galaxies' distance, and it is therefore justified to assume that the molecular medium fills the surface of the quasar continuum source. Assuming a filling factor of 1 , we can derive the average column density over the beam corresponding to the quasar mm continuum emission and its footprint on the galaxy tidal tail. This will be a lower limit to the actual column density,

$$N_{\text{tot}} = \frac{8\pi}{c^3} \frac{\nu^3}{g_J A_{J,J+1}} f(T_x) \int \tau dv, \quad (1)$$

(2) stellar mass estimated from the L_B luminosity (Bell & de Jong 2001).

(3) star formation rate estimated using the FIR luminosity, with the relation $\text{SFR} = L_{\text{FIR}} / (5.8 \times 10^9 L_{\odot})$ compiled by Kennicutt (1998).

(4) Integrated CO line luminosity estimated from the observed CO(1-0) flux (Downes et al. 1993).

(5) Total molecular gas mass estimated assuming a CO-to- H_2 conversion factor $\alpha_{\text{CO}} = 4.36 M_{\odot} (\text{K km s}^{-1} \text{ pc}^2)^{-1}$.

Table 2. NOEMA observations of absorption and emission toward Q0248

	Absorption	Emission
RA	02:51:34.5	02:51:36.04
Dec	43:15:16.0	43:15:10.8
z	0.05151	0.05135
$S_{\text{CO}(1-0)}$	0.25 ± 0.02	29 ± 0.5
ΔV_{CO}	16 ± 1.6	191 ± 2
$S_{\text{CN}(1-0)}$	0.11 ± 0.02	–
ΔV_{CN}	17 ± 3	–

– The absorption position is that of the quasar, the emission position is that of the CO(1-0) peak close to G1 (see Fig. 1).

– The integrated absorption signal is the integrated optical depth in km s^{-1} . In emission, it is the integrated CO flux in Jy km s^{-1} for the whole galaxy

– The ΔV are FWHM, in km s^{-1}

where g_J is the statistical weight of level J , $A_{J,J+1}$ is the Einstein coefficient for transition $J \rightarrow J+1$, and the function $f(T_x)$ is

$$f(T_x) = \frac{Q(T_x) e^{E_J/kT_x}}{1 - e^{-h\nu/kT_x}} \quad (2)$$

We adopt the partition function of local thermal equilibrium (LTE), i.e., $Q(T_x) = \sum g_J e^{-E_J/kT_x}$, where E_J is the energy of level J or $N = J + F$ (for CN) and T_x is the excitation temperature of the CO or CN molecule. For the CN molecule, we detect the two stronger lines at rest frequencies, 113.488 GHz and 113.490 GHz, which are blended at our spectral resolution (they correspond to $J=3/2-1/2$, $F=3/2-1/2$, and $F=5/2-3/2$). We do not detect the three other lines, expected to be five times weaker. We have detected CO(1-0) absorption in front of the quasar, with an optical depth $\tau=0.016$ or $\tau\Delta V = 0.25 \text{ km s}^{-1}$, corresponding to $N(\text{CO}) = 2.9 \times 10^{15} \text{ cm}^{-2}$ or $N(\text{H}_2) = 2.9 \times 10^{19} \text{ cm}^{-2}$, for a common CO/ H_2 abundance ratio of 10^{-4} . For this computation, we have assumed an excitation temperature of $T_x = 15 \text{ K}$. With the same assumptions, the column density of CN is $7.6 \times 10^{12} \text{ cm}^{-2}$. The relative abundance of CN/CO = 2.6×10^{-3} is relatively high for dense clouds, by 1 or 2 orders of magnitude (e.g., Leung et al. 1984), but not necessarily for more diffuse clouds, for which some models predict abundances 100 times higher (Wakelam et al. 2015). The H_2 column density found toward the tidal

Fig. 3. CO(1-0) integrated intensity map of the galaxy G0248 (bottom) seen in emission and its velocity field (top) from our NOEMA observations. The scales are in arcsec, with respect to the phase center RA(2000)= 02h 51m 35.1s, Dec(2000)=43° 15' 14.0", and the box size is 8". The beam is indicated in the bottom left corner. The integrated flux is in $\text{Jy.beam}^{-1} \text{ km s}^{-1}$, and the velocity scale in km s^{-1} , relative to $z=0.05151$.

tail indeed corresponds to that of a diffuse interstellar medium (Welty et al. 2006) (see also Sect. 1).

4.2. Implications of CO emission

Figure 3 displays the NOEMA integrated CO(1-0) emission map and the velocity field of G0248 (zero and first moments of the cube). The central CO(1-0) spectrum is displayed in Fig. 4. For the first time, the CO emission is resolved by our beam of $0.94 \times 0.67''$ and the total extent of the CO emission is $\sim 4 \text{ kpc}$. The morphology is not symmetric, however, as expected for an interacting galaxy. The velocity field shows clear rotation, with the kinematic major axis in the N-S direction. The projected gradient is relatively low, but this can be explained by the almost face-on orientation (inclination $\leq 30^\circ$) of both G1 and G2. The systemic velocities of the two galaxies, obtained through their optical spectrum by Kollatschny et al. (1991), are indicated in figure 4. They are symmetrically located at $\pm 80 \text{ km s}^{-1}$ from the center of the absorption, which is at $z=0.05151$.

With our high spatial resolution, we can now attribute the CO emission to one or the other galaxy of the pair. The galaxies are separated by $3.5'' = 3.5$ kpc, and Hwang & Chiou (2004) find the CO emission centered in the middle of G1 and G2, but they had a synthesized beam of $2''$. As displayed in Table 2, the center of the CO emission coincides clearly with the position of the spiral galaxy G1, and not with the elliptical G2, or with a position in between the two merging galaxies. Within its maximum radial extent of 2 kpc, there is no CO emission detected toward the center of G2. Kollatschny et al. (1991) estimated the V luminosities of both galaxies, $L_V(G1) = 4.5 \times 10^9 L_\odot$ and $L_V(G2) = 9.4 \times 10^9 L_\odot$. Through kinematical arguments, they also derived a total mass for the ensemble of $M_{tot} = 6.7 \times 10^{10} M_\odot$. Assuming comparable mass-to-luminosity ratios for the two galaxies, we can estimate the stellar mass of G1 at $2.2 \times 10^{10} M_\odot$. This estimation is compatible with that obtained from the observed $H\alpha$ and [NII] rotation curve: a maximum rotational velocity of 100 km s^{-1} at a radius of 2 kpc, provided that the inclination of the spiral galaxy G1 is 27° .

The observation of the fundamental CO(1-0) line is the best measure of the total H_2 mass. We compute L'_{CO} , the CO luminosity in units of $\text{K km s}^{-1} \text{ pc}^2$, through integrating the CO intensity over the velocity profile, and over the galaxy extent. The total flux is $S_{CO} dV = 29 \text{ Jy km s}^{-1}$ (see Table 2) very close to the previous values, 24 Jy km s^{-1} with the BIMA interferometer (Hwang & Chiou 2004) and 25 Jy km s^{-1} with the IRAM 30m telescope (Downes et al. 1993), confirming that the interferometer has not resolved out any emission.

This CO luminosity is given by

$$L'_{CO} = 3.2510^7 S_{CO} dV \frac{D_L^2}{v_{rest}^2 (1+z)} \text{ K km s}^{-1} \text{ pc}^2, \quad (3)$$

where $S_{CO} dV$ is the integrated flux in Jy km s^{-1} , v_{rest} the rest frequency in GHz, and D_L the luminosity distance in Mpc. Under the assumption of a standard CO-to- H_2 conversion factor (Bolatto et al. 2013), we compute the H_2 mass using $M_{H_2} = \alpha L'_{CO}$, with $\alpha = 4.36 M_\odot (\text{K km s}^{-1} \text{ pc}^2)^{-1}$. The molecular gas mass is then $M_{H_2} = 1.5 \times 10^{10} M_\odot$.

Given our estimation of the stellar mass of the spiral galaxy G1 above, we can now compute a gas fraction of 40%. This is a high gas fraction, even for the $z = 0.05$ epoch, as determined from the scaling relation of the main sequence (e.g., Tacconi et al. 2018). The gas fraction in G1 is ten times higher than the value expected on the main sequence. The explanation is that G1 belongs to a merging system. The SFR is $74 M_\odot/\text{yr}$ (see Table 1), and the depletion time is $t_{dep} = 200 \text{ Myr}$, i.e., ten times lower than the depletion time on the main sequence. The merging system is therefore in a starburst phase, probably due to the gravitational torques of the interaction, which have driven all the gas reservoir of the G1 spiral galaxy inward. Alternatively, as observed in active starburst galaxies, it is possible to adopt a much lower CO-to- H_2 conversion factor, but then the depletion time would be even lower, which would bring the system even farther from the main sequence.

4.3. $H\text{I}$ absorption

The updated $H\text{I}$ 21cm absorption spectrum toward the quasar is presented in Fig. 2, together with the other absorption lines. We have fitted the spectrum with four Gaussians, and the results are in Table 3. The new $H\text{I}$ absorption spectrum with high spectral resolution allows the discovery of quite narrow components (8 km s^{-1} , implying a kinetic temperature lower than 1400 K),

Fig. 4. CO(1-0) emission spectrum toward the GO248 galaxy center. The zero of the velocity scale ($z = 0.05151$) is centered at the peak of the low resolution $H\text{I}$ 21cm absorption line (Gupta et al. 2018a). The systemic velocity of the two merging galaxies G1 and G2 are indicated. The vertical scale is in mJy beam^{-1} .

together with relatively wide wings (33 km s^{-1}), although the fit is not unique. Within the errors, the integrated 21cm optical depth estimated using this spectrum is consistent with that from the VLA spectrum presented in Gupta et al. (2018b). As expected the molecular absorption is coincident with the narrower (implying colder) and stronger 21cm absorption components at -2.6 and $+8.7 \text{ km s}^{-1}$. The limited spectral resolution and sensitivity of the molecular data (OH, CO, and CN) does not allow us to carry out a more detailed decomposition. The two main and broader components seen in the $H\text{I}$ absorption are only tentatively seen in the OH spectrum, and not in CO or CN. This might be explained by the different sizes of the quasar continuum emission at millimeter and centimeter wavelengths. The radio continuum at 2.3 GHz has an overall extent of 26 mas (27 pc at $z=0.05$; Fey & Charlot (2000)), which is much larger than the size expected at ~ 100 GHz relevant for CO and CN absorption lines.

Table 3. uGMRT observations of absorption lines

Line	Area km s^{-1}	V km s^{-1}	ΔV km s^{-1}	Peak
HI_1	0.11 ± 0.01	-24 ± 1.8	$33. \pm 1.8$	0.9967
HI_2	0.07 ± 0.01	$-10. \pm 1.8$	8 ± 1.8	0.9913
HI_3	0.16 ± 0.01	-2.6 ± 1.8	4.5 ± 1.8	0.9664
HI_4	0.17 ± 0.01	8.7 ± 1.8	12 ± 1.8	0.9871
OH_1	-0.06 ± 0.01	-4 ± 2	17 ± 5	0.9966
OH_2	-0.015 ± 0.01	14 ± 4	8 ± 6	0.9982

- Area is the integrated optical depth
- The ΔV are FWHM; the peaks correspond to the maximum depth of the signal, as shown in Fig. 2

4.4. Absorption upper limits

The wide bandwidth of NOEMA allowed us to search for other possible absorptions from lines falling in our frequency range. There is an H₂CO line at 101.332 GHz; however, the lower level of the transition at 57 K is too high to yield a significant limit. There is CS(2-1) at 97.980 GHz, with a lower level at 2.2 K, and the fundamental O₂ line at 118.750 GHz. These lines were not detected, and we derive 3σ upper limits of $N(\text{CS}) \leq 3.3 \times 10^{12} \text{ cm}^{-2}$ and $N(\text{O}_2) \leq 2.9 \times 10^{17} \text{ cm}^{-2}$, assuming the same excitation temperature of $T_x = 15 \text{ K}$. The molecular oxygen limit is quite high, because the strength of the transition is about 2 orders of magnitude lower than for the CO molecule.

5. Concluding remarks

We reported the discovery of a new CO(1-0) absorption in an intervening galaxy ($z = 0.05$) in front of a background quasar ($z = 1.3$). Millimetric molecular absorptions are still very rare at moderate and high redshift: only six systems have been found (e.g., Combes 2008): three are associated-absorbing systems (i.e., from the AGN host itself), one has been detected recently (Allison et al. 2019), and three are intervening absorbers from gravitational lens systems. To date no simple millimeter molecular absorber has been detected in a normal intervening galaxy without strong lensing, and hence more suitable to study variations of fundamental constants. The absorber in front of Q0248 presented here is thus the first one: the absorbing gas is in a tidal tail without any lensing potential.

With high spatial resolution, the number of detections for local millimeter absorption, in the associated-absorption category, is increasing (e.g., Tremblay et al. 2016), providing extremely useful information, for example disentangling inflow from outflow around AGN. Although intervening H₁ 21cm absorbers are now more frequent with about a 30% detection rate in case of optically selected sight lines (Gupta et al. 2009, 2013; Dutta et al. 2017), the OH absorbers in intervening galaxies are still rare, with an incidence or a number per unit redshift of $n_{\text{OH}} = dN_{\text{OH}}/dz = 0.008$, at $z \sim 0.1$ (Gupta et al. 2018a).

In the present case, the absorption is from relatively diffuse gas, belonging to a tidal tail at about 17 kpc projected distance from the parent G1 galaxy, the gas-rich spiral from the merging pair. The column density is therefore quite low, and the depth of the absorption rather small, less than 2%. In the near future, the increased sensitivity of ALMA, NOEMA, and large blind surveys with SKA precursors such as MALS (e.g., Gupta et al. 2016; Allison et al. 2016) will make it possible to discover such weak absorbing systems, which was impossible before.

Acknowledgements. We warmly thank the referee for the constructive comments and suggestions. We thank the GMRT and IRAM staff for their support during the observations, and in particular Mélanie Krips during the reduction of NOEMA data. We acknowledge the use of ARTIP. ARTIP was developed by researchers and developers at ThoughtWorks India Pvt. Limited and IUCAA. GMRT is run by the National Centre for Radio Astrophysics of the Tata Institute of Fundamental Research. The National Radio Astronomy Observatory is a facility of the National Science Foundation operated under cooperative agreement by Associated Universities, Inc. This work is based on observations carried out under project number W17CE with the IRAM NOEMA Interferometer. IRAM is supported by INSU/CNRS (France), MPG (Germany), and IGN (Spain). The Common Astronomy Software Applications (CASA) package was developed by an international consortium of scientists based at the National Radio Astronomical Observatory (NRAO), the European Southern Observatory (ESO), the National Astronomical Observatory of Japan (NAOJ), the Academia Sinica Institute of Astronomy and Astrophysics (ASIAA), the CSIRO division for Astronomy and Space Science (CASS), and the Netherlands Institute for Radio Astronomy (ASTRON) under the guidance of NRAO.
