ABSTRACT

Transition metal ions impurities in microbialites have been previously suggested as paleoenvironmental and/or paleobiological proxies. However, how metals are incorporated into microbialites remains poorly known. Here, in order to assess the distribution and speciation of Fe in modern microbialites, we conducted bulk x-ray diffraction, infrared spectroscopy, x-ray absorption near-edge structure (XANES) spectroscopy, electron microscopy and x-ray microscopy analyses on samples collected from shallow depths in five alkaline lakes in Mexico: Lake Alchichica, Lake La Preciosa, Lake Atexcac, Lake La Alberca de Los Espinos and Lake Pátzcuaro. A range of Fe contents were measured in these microbialites, from low ($\sim$0.12 wt.%) to relatively high ($\sim$2.2 wt.%). Fe was distributed heterogeneously in microbialites, mostly localized as hotspots or sometimes arranged as discrete laminae. Fe was mostly trivalent in all microbialites and was incorporated into diverse authigenic phases, the proportion of which varied among microbialites. Authigenic phases included Fe-bearing Mg-phyllosilicates such as kerolite and/or stevensite, i.e. $(Mg,Fe(II),Fe(III))_3Si_4O_{10}(OH)_2 \cdot nH_2O$ and Fe-Mg layered double hydroxides (LDH), i.e. pyroaurite $[Mg(II)_6Fe(III)_2(CO_3)(OH)_{16} \cdot 4H_2O]$ and/or iowaite $[Mg(II)_6Fe(III)_2Cl_2(OH)_{16} \cdot 4H_2O]$, together with Fe-(oxyhydr)oxides. Carbonate phases were negligible carriers of Fe in all lakes. Iowaite/pyroaurite phases, which have often been found as low temperature alteration products in serpentinites, were surprisingly observed in Lake Alchichica, whereas Fe-bearing kerolite/stevensite was present in Lake La Preciosa, Lake Atexcac, Lake La Alberca de Los Espinos and Lake Pátzcuaro. Fe present in these shallow water microbialites may be originated from groundwater seepage derived from adjacent Fe-rich volcanic rocks. We suggest that the occurence of iowaite/pyroaurite *vs* authigenic Fe-bearing kerolite/stevensite depends on the orthosilicic acid concentration in the lakes.

2

54 Pyroaurite/iowaite may form and stay preserved in Lake Alchichica because of the low

55 $[H_4SiO_4]$ as well as high alkalinity, $[Mg^{2+}]$, $[CO_3^{2-}]$, $[Cl^-]$ and pH (~9) prevailing in this lake,

56 while in other lakes, where $[H_4SiO_4]$ is higher (above ~0.4 mM), Fe-bearing kerolite or

57 smectite phases are formed. Overall, the message carried by the Fe-bearing mineral phases in

58 these modern microbialites is multifold: Fe-bearing phases within microbialites may contain

59 some information on environmental conditions (e.g., $[H_4SiO_4]$) as well as on geochemical

60 processes implicated during their formation (e.g., seepage of anoxic Fe-bearing groundwater).

61 Considering the reactivity of pyroaurite/iowaite and kerolite/stevensite and their possible

62 transformation into diverse mineral phases upon microbial activity, burial and diagenesis, a

63 careful appraisal of Fe speciation using a similar combination of bulk and microscopy

64 analyses is required in order to better assess the origin of Fe in ancient microbialites.

65

66 **1. INTRODUCTION**

67

68 Microbialites are organo-sedimentary rocks formed in close association with

69 microorganisms (Burne and Moore, 1987). These rocks have been repeatedly suggested to

70 record information on the environmental conditions under which they formed (e.g., Chagas et

71 al., 2016). Part of this information can be retrieved through the analysis of their chemical

72 composition, including their trace and/or transition element content (Petrash et al., 2016). For

73 example, some modern microbialites have been shown to retain shale-normalized rare earth

74 element (REE_{SN}) patterns similar to those of seawater, suggesting that ancient microbialites

75 may be used to infer past chemical variations of seawater (Webb and Kamber, 2000).

76 Alternatively, the trace element and transition metal content in microbialites may be impacted

77 by some biological fractionation processes and provide information on past microbial

78 activities (Kamber and Webb, 2007). The trace element chemical patterns may also be

79 modified secondarily by diagenetic processes, as shown for some ca 1.88 Ga old stromatolites

80 from the Gunflint Formation (Petrash et al., 2016).

81   The Fe chemistry in microbialites has been specifically investigated as a potential

82 source of paleoenvironmental information. For example, Von Blanckenburg et al. (2008)

83 suggested that most of Fe found in some modern and ancient marine microbialites occurred in

84 hydrogenous carbonates, rather than Fe and Mn-hydroxides. If this were true, the Fe isotope

85 composition of ancient microbialites could be used to record ancient seawater Fe chemistry.

86 Alternatively, Fe can be actively processed and transformed by diverse microorganisms,

87 serving as an electron donor or acceptor for various microbial metabolisms and/or as a co-

88 factor for several enzymes (e.g., Weber et al., 2006; Cornelis, 2014). For example, Planavsky

89 et al. (2009) interpreted the Fe isotope composition of 1.89 Ga old microbialites as the result

90 of microbially-mediated Fe precipitation involving Fe-oxidizing bacteria. Overall, there is a

91 need to better understand how Fe becomes sequestered within microbialites.

92   Modern microbialites may form differently from ancient microbialites, especially from

93 the Archean. Therefore, great care should be taken when applying interpretations from the

94 modern to the past (e.g., Bosak et al., 2013). Yet the study of metal chemistry in modern

95 microbialites may serve as a model case to better assess the complex processes involved in Fe

96 sequestration within microbialites and the diversity of primary Fe-bearing mineral phases that

97 may form. Fe was sometimes abundant in ancient microbialites, especially when ferruginous

98 conditions were prevailing in aqueous environments (e.g., Von Blanckenburg et al., 2008). In

99 contrast, low Fe contents are expected in the authigenic phases composing modern

100 microbialites, which usually form in well oxygenated and alkaline water, because of the low

101 solubility of Fe under these conditions (Schwertmann, 1991). Nevertheless, some modern

102 shallow-water microbialites from the alkaline Mexican Lakes Alchichica, Atexcac and La

103 Preciosa have been recently reported to contain relatively high amounts of Fe, i.e. >0.44 wt.%

104   of Fe_2O_3 (Kaźmierczak et al., 2011; Zeyen et al., 2015). In order to understand the origin of

105   this enrichment in Fe and determine whether this is due to authigenesis or detrital input, we

106   characterized the speciation of Fe in Lake Alchichica and Atexcac microbialites as well as in

107   microbialites from three other distinct alkaline lakes located in the trans Mexican volcanic

108   belt. For this purpose, we combined bulk x-ray diffraction, Fourier-transform infrared

109   spectroscopy and x-ray absorption near-edge structure (XANES) spectroscopy analyses,

110   coupled with scanning and transmission electron microscopies as well as x-ray microscopy

111   analyses. Overall, this enabled us to develop a consistent assessment of the Fe-bearing

112   mineral phases composing these diverse modern microbialites, and thereby infer some of the

113   geochemical processes that give rise to Fe enrichments in microbialites.

114

115   **2. MATERIALS AND METHODS**

116

117   **2.1. Samples**

118   **2.1.1 Microbialite samples**

119   Field campaigns were conducted in June 2007, January 2012 and May 2014. Seven

120   samples of modern microbialites were collected in five lakes: Alchichica, La Preciosa,

121   Atexcac, La Alberca de Los Espinos and Pátzcuaro, all located within the trans Mexican

122   volcanic belt (TMVB), a continental volcanic arc with an East-West orientation (Ferrari et al.,

123   2012). Lake Pátzcuaro is older than 30,000 years and is a lava-dammed basin (Israde-

124   Alcántara et al., 2005). The other lakes are maar lakes formed by phreato-magmatic

125   explosions during the Pleistocene (Armienta et al., 2008; Siebe et al., 2014). Atexcac, La

126   Preciosa and Alchichica maars are composed of tuff rings (Carrasco-Núñez et al., 2007). La

127   Alberta de Los Espinos maar is a tuff cone (Siebe et al., 2014). Table 1 summarizes the main

128   physical and geochemical parameters of these lakes.

129   Lake Alchichica harbored a high density of microbialites forming meter-scale

130   bioherms all around the lake (Fig. SI-1a and d). The carbonate mineralogy and microbial

131   diversity of Lake Alchichica microbialites have been extensively studied (Kaźmierczak et al.,

132   2011; Couradeau et al., 2011; Couradeau et al., 2013; Gérard et al., 2013; Saghaï et al., 2015;

133   Saghaï et al., 2016). Many microbialites were white in cross-section, but some had a darker,

134   orange to brown color as reported by Kaźmierczak et al. (2011). These orange-brown

135   microbialites were located on the West shore of the lake (Fig. SI-1a). There, the crater rim

136   was particularly steep due to the outcrop of a basaltic scoria cone (Fig. SI-1b). In the present

137   study, we investigated Fe speciation in one sample of a brown, living (i.e. underwater and

138   covered by a biofilm) microbialite sampled in May 2014 on the West shore of Lake

139   Alchichica (AL2014-15) (Fig. SI-1c), and two white, living microbialites from the North

140   shore, collected in June 2007 at a depth of about 0.1 and 4 meters and named AL13 and

141   AL66, respectively (Fig. SI-1e).

142   Microbialites from Lake La Preciosa and Lake Atexcac were described by Zeyen et al.

143   (2015). Fossil (i.e. dry and not covered by a biofilm) microbialites formed steep bioherms on

144   the North shore of Lake La Preciosa (Fig. SI-1f). A grey fossil microbialite (Preciosa05-2012)

145   was analyzed in the present study (Fig. SI-1g). Microbialites from Lake Atexcac formed a

146   steep wall superimposed on the crater walls (Fig. SI-1h). Here, a living microbialite showing

147   a grey to orange color inside (ATX-2C1-2012) was sampled on the northern wall of the lake

148   (Fig. SI-1i). Lake La Alberca de Los Espinos harbored decimeter-sized living microbialites

149   restricted to a small area close to the West shore of the lake. Here, the studied sample

150   contained some black small columns and orange pustules (AlbEsp2014-01) (Fig. SI-1j and k).

151   Finally, living microbialites were collected on the north-eastern shore of Lake Pátzcuaro.

152   Here, we studied a decimeter-sized brownish living laminated stromatolite (Patz2014-02),

153   encrusting a basaltic rock (Fig. SI-1l and m). To our knowledge, microbialites from Lake

154 Pátzcuaro and Lake La Alberca de Los Espinos have not been reported before.

155

2.1.2. Synthetic model compounds

Syntheses of nanocrystalline Fe(II):talc and Fe(III):talc

158   Talc model compounds containing Fe(II) or Fe(III), partially substituted for Mg,

159 referred to as nano-Fe(II):talc and nano-Fe(III):talc respectively, were synthesized using the

160 protocol described by Juillot et al. (2006), with the stoichiometry $Fe_{0.05}Mg_{2.95}Si_4O_{10}(OH)_2$,

161 close to that measured by electron microprobe in Atexcac microbialites (Zeyen et al., 2015).

162 For this purpose, a solution of 200 ml of sodium metasilicate $Na_2SiO_3 \cdot 5H_2O$ (0.1 M) was

163 prepared. Then, for the synthesis of nano-Fe(III):talc, a mixture of $Fe(III)Cl_3 \cdot 6H_2O$ (0.01 M)

164 and $MgCl_2 \cdot 6H_2O$ (0.29 M) was homogenized. Fifty milliliters of the Fe/Mg mixture were

165 added to 200 ml of the sodium meta-silicate solution. After this step, the pH of the solution

166 was 11.4. The pH was adjusted to around 10.9 using HCl (1M) and the solution was

167 homogenized for 30 minutes. Precipitates were centrifuged at 9000 g for 10 minutes and

168 washed four times with milli-Q water before being transferred into 8 glass serum bottles

169 sealed with a butyl rubber stopper and an aluminum cap (0.5 g of hydrated precipitate per

170 flask), each containing 100 ml of water. Flasks were placed in an oven for 7 days at 80°C.

171 Finally, the solutions were centrifuged at 9000 g for 10 minutes and washed four times with

172 milli-Q water. Precipitates were dried in the desiccator overnight. For the synthesis of nano-

173 Fe(II):talc, the same protocol as above was followed except that the synthesis was carried out

174 in an anaerobic glove box using O_2-free milli-Q water, and $FeCl_2 \cdot 4H_2O$ was used as a Fe(II)

175 source. For this synthesis, the precipitate obtained before the aging period at 80°C was also

176 washed and dried, and is designed hereafter as nano-Fe(II):talc-gel. In addition, in order to

177 mimic oxidation of the structural Fe(II) in talc, a sample of nano-Fe(II):talc-gel dry powder

178 was oxidized in an excess of 1 ml of 3% H_2O_2 for about 5 hours before being rinsed with

179   milli-Q water and air dried. The resulting sample was referred to as nano-Fe(II):talc-gel H_2O_2

180   oxidized.

181

182   *Synthesis of Fe(III):hydrotalcite*

183   Hydrotalcite containing Fe(III) as impurity, referred to as Fe(III):hydrotalcite, was

184   synthesized with the following stoichiometry: $Mg_{0.75}Al_{0.24}Fe(III)_{0.01}OH_2(CO_3)_{0.125}$. For this

185   purpose, a 100 mL solution containing $MgCl_2 \cdot 6H_2O$ (0.06 M), $Al_2(SO_4)_3 \cdot 18H_2O$ (0.01 M)

186   and $Fe(III)Cl_3 \cdot 6H_2O$ (0.0008 M) was titrated with a mixture of NaOH (1.6 M) and Na_2CO_3

187   (0.1 M) to pH 10. The solution was stirred for one hour. The precipitate was then centrifuged

188   four times at 9000 g for 10 minutes and rinsed with milli-Q water. Finally, the precipitate was

189   placed in a desiccator overnight. The purity of the synthesized phases was checked by FTIR

190   and/or XRD (Fig. SI-2).

191

192   **2.2 Methods**

193   A quantity of about 10 g for each microbialite sample was finely ground in an agate

194   mortar and aliquots of the same powdered sample were used for the different bulk analyses.

195

196   **2.2.1. Bulk chemical analyses of microbialites**

197

198   Bulk chemical compositions of microbialite samples were determined by the *Service*

199   *d'Analyse des Roches et Minérau*x (SARM, Centre de Recherches Pétrographiques et

200   Géochimiques, Nancy, France). About 2 g of ground powders were used for these analyses.

201   Major element analyses were performed using an ICP-AES ICap 6500 (Thermo Fischer) after

202   alkali fusion of rock samples with $LiBO_2$ followed by dissolution in HNO_3. The uncertainties

203   of the major element measurements were between 1% and 25% depending on their

204   concentrations (Table 2).

205

206   **2.2.2. Bulk mineralogical analyses of microbialites**

207

208   *X-ray diffraction (XRD)*

209   The bulk mineralogical composition of microbialites was determined by XRD. About

210   1 g of each microbialite powder was deposited on an aluminum sample holder. XRD

211   measurements were performed using a Panalytical X'Pert diffractometer equipped with a

212   cobalt anode (Co-Kα). Data were recorded at 40 kV and 40 mA in continuous-scan mode

213   between 5 and 90° (2θ) with a step of 0.008°/s and a total counting time of ~3 h per scan.

214   XRD data were analyzed using the PANalytical X'Pert Highscore software for background

215   subtraction, peak finding, and matching with XRD patterns of reference compounds from the

216   International Crystal Structure Database (ICSD, Fachinformationszentrum Karlsruhe,

217   Germany; US Institute of Standards and Technology, USA).

218

219   *Fourier transform infrared (FTIR) spectroscopy*

220   For FTIR spectroscopy analyses, 2.5 mg of microbialite powder and 300 mg of

221   potassium bromide (KBr) were mixed and ground in an agate mortar. A KBr pellet was

222   prepared for each microbialite sample using a vacuum press under 8 tons for 1 minute. Pellets

223   were placed overnight in an oven (95°C) to remove the adsorbed water and were pressed a

224   second time. Transmission spectra were recorded as 210 replicate scans between 400 and

225   4000 cm^{-1} with 1 cm^{-1} resolution, using a Nicolet 6700 FTIR spectrometer.

226

227   **2.2.3. Analyses of bulk Fe speciation by x-ray absorption near-edge structure (XANES)**

228   **spectroscopy**

9

229

230   X-ray absorption near-edge structure (XANES) data of 7 microbialite samples (AL66,

231 AL13, AL2014-15, Preciosa05-2012, ATX-2C1-2012, AbEsp2014-01 and Patz2014-02) were

232 collected at the Fe K-edge in the fluorescence detection mode on beamline BM23 at the ESRF

233 (Grenoble, France) using a Si(111) double crystal monochromator and a 13 elements Ge array

234 detector. Duplicate data were recorded for sample AL66 on beamline BM30B FAME at the

235 ESRF (Grenoble, France) using a Si(220) double crystal monochromator with sagittal

236 focusing of the second crystal, and a 30 elements Ge array detector. Sample pellets were

237 prepared using 130-230 mg of powder for all samples but the AL2014-15 sample, for which 5

238 mg of powder were mixed with 50 mg of cellulose. In addition, XANES spectra were

239 collected for 3 model compounds: Fe(III):hydrotalcite, nano-Fe(II):talc and nano-Fe(III):talc.

240 This was achieved in transmission detection mode at the BM23 beamline on pellets prepared

241 by mixing 20-30 mg sample with 40-30 mg cellulose. Analyses were conducted at a

242 temperature of ~10 K. Energy was calibrated by setting to 7112 eV the first inflection point of

243 the Fe K-edge XANES spectrum of a reference Fe(0) foil, recorded simultaneously with the

244 samples. For each microbialite sample and model compound, 2–8 scans were recorded,

245 depending on the Fe concentration. XANES spectra were acquired from a range of 7000–

246 7575 eV. The background Fe fluorescence signal arising from the excitation of the beamline

247 components by diffuse scattering (e.g. sample chamber inner walls and Fe impurities in Be

248 windows) was collected by measuring a XANES spectrum on a pure cellulose pellet. All data

249 were averaged and normalized using the ATHENA software (Ravel and Newville, 2005).

250   Fe K-edge XANES spectra of the microbialite samples were analyzed using a linear

251 combination least-squares fitting (LC-LSF) procedure that was performed with a custom-built

252 software based on a Levenberg–Marquardt least-squares minimization algorithm (Hohmann

253 et al., 2011; Stetten et al. 2017). A large set of already available Fe K-edge XANES spectra of

254 natural and synthetic model compounds was already available for this fitting procedure. This

255 dataset included a large variety of synthetic Fe compounds such as Fe(III) (oxyhydr)oxides,

256 e.g. goethite (alpha-FeOOH) and 6-line ferrihydrite (Maillot et al., 2011; Hohmann et al.,

257 2011) and siderite ($FeCO_3$) (Dublet et al., 2014), and 2) natural phyllosilicates (Cosmidis et

258 al., 2014; Othmane et al., 2013), such as serpentine from New Idria Mining District (CA,

259 USA) (Dublet et al., 2012; Noël et al., 2014) and illite from Le Puy-en-Velay, France, i.e.,

260 $Na_{0.01}K_{0.64}Ca_{0.06}(Al_{1.19}Fe(III)_{0.36}Mg_{0.43}Ti_{0.04}Mn_{0.01})(Si_{3.53}Al_{0.47})O_{10}(OH)_2$ (Ildefonse et al.,

261 1998). This latter model compound, referred to as Fe(III):illite hereafter, was used as a proxy

262 for structural Fe(III) in a dioctahedral 2:1 phyllosilicate. The background Fe signal from the

263 beamline was systematically included as an additional component in the XANES LC-LSF

264 procedure and accounted for 1 to 28% of the measured signal (Table SI-1), depending on Fe

265 concentration and the amount of analysed microbialite sample. The quality of the LCF fits

266 was estimated by a reduced chi-square parameter $\chi^2_R = n / (n\text{-}p) \, \Sigma \, [\mu_{exp} - \mu_{calc}]^2$ where n is

267 the number of independent parameters corresponding to the energy range divided by the

268 natural width of the Fe K levels reported by Krause and Oliver (1979). The uncertainty on the

269 fitting components was estimated by $3 \times \sqrt{VAR(p)\,\chi^2_R}$, where $VAR(p)$ is the variance of

270 parameter p returned by the Levenberg–Marquardt routine for the lowest χ^2_R value (Stetten et

271 al., 2017).

272

273 **2.2.4. Microscopy analyses of microbialites**

274

275 *Sample preparation for microscopy analyses*

276 Some microbialite samples (ATX-2C1-2012, Preciosa05-2012 and AlbEsp2014-01)

277 were sawed to obtain ~5 mm thick sections and polished down to a ¼ of micron of surface

278 roughness with diamond polishing compounds. Then, they were rinsed in an ultrasonic

279   cleaning bath with pure ethanol. Finally, polished sections were dried overnight in a

280   desiccator. Samples were mounted on 2.5 cm wide aluminum stubs using double-sided carbon

281   tape. Alchichica and Pátzcuaro microbialite samples (AL13, AL66, AL2014-15 and Patz-

282   2014-02) were dehydrated in a gradual series of ethanol baths (30%, 50%, 70%, 90% and

283   100%), and progressively impregnated with hard grade LR-white resin (Polysciences, Inc.).

284   The samples were incubated for 18 h at 4-6°C in 1:2 (1:1 for AL13 and AL66 samples) and

285   then in 2:1 mixture of LR-white/ethanol, and finally in pure LR-white resin. After 3 h at room

286   temperature, samples were embedded in pure LRwhite resin for 1 h at 40°C and then for 24 h

287   at 60°C. After polymerization, transverses sections were cut with a diamond wire to obtain ~2

288   mm thick sections and polished until 1/4 μm of surface roughness. All samples were carbon-

289   coated, except AlbEst2014-01, which was platinum-coated.

290

291   *Scanning electron microscopy (SEM)*

292   Scanning electron microscopy analyses were performed using a Zeiss ultra 55 field

293   emission gun (FEG) SEM. Backscattered electron (BSE) images were acquired using an angle

294   selective backscattered (AsB) detector at an accelerating voltage of 15 kV and a working

295   distance of ~7.5 mm. The elemental composition of mineral phases was determined by energy

296   dispersive x-ray spectrometry (EDXS) using an EDS QUANTAX detector. EDXS data were

297   analyzed using the ESPRIT software package (Bruker).

298

299   *Micro x-ray fluorescence (*μXRF*) mapping*

300   X-ray fluorescence images were collected on AL13 and AL66 microbialite samples at

301   the Stanford synchrotron radiation lightsource (SSRL) using beam line 2–3. The incident

302   energy was set to 11 keV using a Si (111) double crystal monochromator with the storage ring

303   Stanford Positron Electron Accelerating Ring (SPEAR) containing 500 mA in top-off mode at

304   3.0 GeV. The fluorescence lines of the elements of interest, as well as the intensity of the total

305   scattered X-rays, were monitored using a Si drift Vortex detector (SII NanoTechnology USA

306   Inc.) equipped with Xspress3 pulse processing electronics (Quantum Detectors). The raw

307   spectra were binned at the time of collection into regions of interest representing the peak

308   areas of the fluorescence emission. The entire fluorescence spectrum was also collected at

309   each data point. The microfocused beam of 2x2μm was provided by a Pt-coated Kirkpatrick-

310   Baez mirror pair (Xradia Inc.). The incident and transmitted x-ray intensities were measured

311   with nitrogen-filled ion chambers. Samples were mounted at 45° to the incident x-ray beam

312   and were spatially rastered in the microbeam using a Newport VP-25XA-XYZ stage. Beam

313   exposure was 50 ms per pixel. Image data was processed using the MicroAnalysis Toolkit

314   (Webb, 2011). The fluorescence regions of interest were corrected for any variations in the

315   incident beam intensity, and placed on the same absolute magnitude scale for each individual

316   element (Fe, Ca) for comparison between samples.

317

318   *Focused ion beam (FIB) sectioning*

319   Four ultrathin electron-transparent foils were cut from polished sections AL13, AL66,

320   AL2014-15 and ATX-2C1-2012 by focused ion beam milling using a FEI Strata Dual-beam

321   235 instrument operating at 30 kV and 5 nA following the FIB lift-out method as described by

322   Benzerara et al. (2005). Before milling, a platinum strap was deposited onto the region of

323   interest of the sample. After *in situ* transfer to a copper grid, the foil was thinned down to

324   around 100 nm with a Ga^+ beam current of about 100 pA and at glancing angle.

325

326   *Transmission electron microscopy (TEM)*

327   FIB foils were analyzed by a JEOL 2100F transmission electron microscope (TEM)

328   operating at 200 kV. This microscope is equipped with a FEG, an ultra-high resolution pole

329   piece, a Gatan energy filter GIF 2001, a JEOL detector with an ultrathin windowing detection

330   of light elements, and a scanning TEM (STEM) device, which allows Z-contrast imaging in

331   high angle annular dark field (HAADF) mode. Elemental mapping was acquired by EDXS in

332   the STEM mode, using the JEOL software Analysis Station. Selected area electron diffraction

333   (SAED) patterns were recorded to identify mineral phases and assess their crystallinity.

334   SAED patterns were processed using the Image J software in order to measure *d*-spacings.

335   The Crystalmaker software was used to index diffraction patterns.

336

337   *Scanning transmission x-ray microscopy (STXM)*

338   FIB foils extracted from Alchichica (AL13 and AL66) and Atexcac (ATX-2C1-2012)

339   microbialite samples were analyzed by STXM at the C K-edge and the Fe $L_{2,3}$-edges.

340   Analyses were performed on beamline 11.0.2.2 at the Advanced Light Source (Berkeley,

341   USA), using a 25 nm zone plate. Energy calibration was achieved using the well-resolved 3p

342   Rydberg peak of gaseous CO_2 at 294.96 eV. Data included image stacks, from which XANES

343   spectra and maps were retrieved. The aXis2000 software (Hitchcock, 2012) was used for data

344   processing. More details on the principles of STXM can be found in Bourdelle et al. (2013).

345

346   **3.   RESULTS**

347

348   **3.1. Bulk chemical composition of Mexican microbialites**

349   Microbialites from the different lakes showed diverse Fe contents (Table 2). Fe

350   content in the microbialites from Preciosa05-2012 (Lake La Preciosa), AlbEsp2014-01 (Lake

351   La Alberca de Los Espinos), ATX-2C1-2012 (Lake Atexcac), and Patz2014-02 (Lake

352   Pátzcuaro) ranged between 0.31 ± 0.02 wt.% and 0.62 ± 0.03 wt.%. In Lake Alchichica, the

353   white microbialites from the North shore (AL13) had a low Fe content of 0.12 ± 0.01 wt.%,

354   whereas the brown microbialites from the West shore (AL2014-15) contained a much higher

355   Fe content of 2.24 ± 0.04 wt.%.

356   While Al and K contents correlated positively together (Fig. SI-3a), no correlation was

357   detected between the Fe content and the Al, K or Ti contents of microbialites (Fig. SI-3b-c-d).

358   For example, sample AL2014-15 had the highest Fe content but a Ti content below the

359   detection limit (Table 2, Fig. SI-3d). This suggested that Fe was predominantly carried by

360   non-detrital phases

361

362   **3.2. Fe bulk speciation in Mexican microbialites**

363   In order to obtain further insight on the identity of the mineral phases hosting Fe,

364   XANES spectroscopy measurements were conducted at the Fe K-edge. These analyses were

365   complemented by XRD and FTIR analyses for mineral identification. Altogether, these

366   analyses showed that Fe-speciation in Alchichica microbialites (AL13, AL66 and AL2014-

367   15) clearly differed from that in the other lakes.

368

369   **3.2.1. Speciation of Fe in microbialites from Lake Alchichica**

370   Our best LC-LSF results for the Fe K-edge XANES spectra of all the Alchichica

371   microbialites (AL2014-15, AL66 and AL13) were obtained by including a significant to

372   major Fe(III):hydrotalcite component in the fits (Figs. 1 and SI-4; Tables 3 and SI-1), up to

373   100% in the AL66 spectrum. This component was interpreted here as a proxy for Fe(III)-

374   bearing layered double hydroxide (LDH), i.e., an anionic clay, with the general stoichiometry

375    $[M(II)_{1-x}M(III)_x(OH)_2][A^{n-}_{x/n}]\cdot mH_2O$, where M(II) (e.g., Mg(II)) and M(III) (e.g., Fe(III)) are

376   di- and tri-valent cations in the octahedral sites within the hydroxide layers and A^{n-} (e.g., Cl^-

377   or CO_3^{2-}) is an exchangeable interlayer anion (Mills et al., 2012). Goethite and ferrihydrite

378   fitting components were also found in the AL2014-15 spectrum, while nano-Fe(II):talc was

379   needed to fit the AL13 spectrum. The nano-Fe(II):talc component was considered as a proxy

380   for Fe(II) in a trioctahedral 2:1 phyllosilicate structure. These XANES results indicated that

381   AL2014-15 and AL66 microbialites contained Fe as Fe(III) only, whereas around 30% of Fe

382   in AL13 microbialite was in the form of Fe(II).

383   FTIR and XRD analyses showed that AL13 and AL66 microbialites were mainly

384   composed of hydromagnesite ($Mg_5(CO_3)_4(OH)_2 \cdot 4H_2O$) with lower amounts of aragonite

385   ($CaCO_3$), whereas AL2014-15 was mostly composed of aragonite with lower amounts of

386   hydromagnesite (Figs. 2 and 3). In agreement with XANES analyses, the weak peaks at 7.59

387   Å (13.4° 2Θ) and 3.79 Å (27.3° 2Θ) in the XRD pattern of the Fe-rich AL2014-15 sample

388   (2.23 wt.%; Table 3) were consistent with the (003) and (006) Bragg reflections of LDH,

389   respectively (Fig. 2). Accordingly, a peak at 1384 cm^{-1} was also detected in the same sample

390   by FTIR spectroscopy (Fig. 3a) and could be interpreted as the carbonate asymmetric

391   stretching mode (v_3CO_3) in LDH (Ross et Kodama, 1967; Braithwaite et al., 1994; Frost and

392   Erickson, 2004), indicating the presence of a CO_3-containing LDH phase. This peak has been

393   also detected in aragonite by Jones and Jackson (1993), although we did not observe it in the

394   aragonite sample from Molina, Aragon, Spain in the RRUFF database (RRUFF ID: R040078;

395   data not shown). The v_3CO_3 FTIR peak at 1384-1385 cm^{-1} possibly indicative of LDH (e.g.,

396   pyroaurite and/or iowaite) was also detected in the Fe-poor AL13 and AL66 sample as a faint

397   shoulder of an intense band attributed to hydromagnesite (Fig. 3c). LDH was not detected by

398   XRD in these samples (Fig. 2), which could be explained by the very low Fe contents in these

399   samples (e.g. 0.13 wt.% in AL13; Table 2). No peak at ~3680 cm^{-1}, indicative of Mg_3-OH

400   stretching bands, characteristic of Mg in octahedral coordination such as in kerolite (Tosca et

401   al., 2011), was observed for sample AL13. Moreover, such a phase was not detected by XRD

402   in this sample, suggesting that if present, it was only in minute amount. The (101) Bragg

403   reflection at 4.18 Å (e.g., 24.7° 2Θ) of goethite (Schwertmann and Cornell, 2000) was not

404   detected by XRD in AL2014-15, possibly because of overlap with the aragonite and

405　hydromagnesite patterns. Ferrihydrite could not be detected by XRD possibly owing to its

406　nanocrystalline structure (Table 2).

407

408　**3.2.2. Speciation of Fe in microbialites from Lakes La Preciosa, Atexcac, La Alberca de**

409　**Los Espinos and Pátzcuaro**

410　　　The Fe K-edge XANES spectra of microbialites from La Preciosa, Atexcac, La

411　Alberca de Los Espinos and Pátzcuaro were all best fitted with a combination of Fe:clay

412　components, namely nano-Fe(II): and/or nano-Fe(III):talc and Fe(III):illite (Figs. 4 and SI-4;

413　Tables 3 and SI-1). Linear fits with other model compounds, such as 1:1 phyllosilicate model

414　compound (e.g., serpentine), provided lower quality fits. The nano-Fe(II):talc fitting

415　component was considered as a proxy for Fe(II) substituting for Mg(II) in the octahedral layer

416　of a trioctahedral 2:1 phyllosilicate, which was confirmed by a shell-by-shell analysis of this

417　model compound (Materials and methods SI-1; Fig. SI-5; Table SI-2). Besides, the local

418　structure around Fe in the synthetic nano-Fe(III):talc fitting component was close to that in

419　the nano-Fe(II):talc-gel oxidized by H_2O_2 and considered as a proxy for the poorly ordered

420　oxidation byproduct of nano-Fe(II):talc (Figs. SI-5 and SI-6). The Fe K-edge EXAFS spectra

421　of these Fe(III)-bearing talc model compounds significantly differed from those of

422　ferrihydrite and illite (Fig. SI-6), indicating different local structures around Fe(III) in these

423　three compounds (Table SI-2). Moreover, these three compounds could also be well

424　distinguished by XANES as shown in Figs. 1 and 4. Fe(III):illite was considered as a proxy

425　for Fe(III) in the octahedral layer of a dioctahedral 2:1 phyllosilicate in the LC-LSF XANES

426　analysis of the microbialite samples. A large fraction of Fe (69-73%) was present in a

427　nanocrystalline trioctahedral 2:1 phyllosilicate in the Preciosa05-2012 and ATX-2C1-2012

428　samples with 22-26% of total Fe as Fe(II). The nanocrystalline trioctahedral 2:1 phyllosilicate

17

429   fraction was slightly lower in the AlbEsp201-01 (57%) and Patz2014-02 (67%) samples as

430   well as the Fe(II) to total Fe proportion (9-10% of total Fe) (Tables 3 and SI-1).

431   Bulk XRD analyses showed that the major mineral phases composing these

432   microbialites were: aragonite and calcite in La Preciosa; aragonite, calcite and

433   hydromagnesite in Atexcac; calcite and monohydrocalcite in La Alberca de Los Espinos;

434   calcite, monohydrocalcite and aragonite in Pátzcuaro (Fig. 5). In addition, broad peaks at 4.5

435   Å (22.8° 2Θ), 2.5 Å (42.3° 2Θ) and 1.5 Å (72.1° 2Θ) were detected in XRD patterns of

436   Preciosa05-2012, ATX-2C1-2012 and Patz2014-02. These peaks may correspond to *d*-

437   spacings at 4.55, 2.48 and 1.52 Å corresponding to two dimensional *hk* diffraction bands

438   (respectively (02-11), (13-20) and (06-33)) characteristic of poorly ordered layer silicate such

439   as hydrated talc (kerolite) or trioctahedral smectite phases (stevensite) (Brindley et al., 1955;

440   Brindley et al., 1977) and/or dioctahedral Fe-smectite such as nontronite (Decarreau et al.,

441   2008). Moreover, faint shoulders at ~11Å (9.3° 2Θ) and ~10 Å (10° 2Θ) in the XRD patterns

442   of the Preciosa05-2012 and Patz2014-02 samples, could correspond to basal reflections of

443   poorly ordered smectite and talc phases, respectively (Fig. 5). The near absence of the (001)

444   reflection could be consistent with a strong phase disorder and/or with the presence of

445   nanophases(s). Some kerolite/stevensite/nontronite was also present in AlbEsp2014-01 as

446   shown by a faint peak at 4.5 Å (22.8° 2Θ) (Inset Fig. 5). In contrast, XRD patterns were not

447   suggestive of 1:1 silicates (e.g., serpentine). For example, the (001) peak of lizardite (RRUFF

448   ID: R060006) or antigorite (RRUFF ID: R070228) at 7.27 Å was not observed. Consistently,

449   FTIR spectra of all four microbialites showed one peak at 1020-1026 cm^{-1} (Fig. 6a),

450   interpreted as Si-O stretching in tetrahedral vibration in a 2:1 layered configuration of

451   tetrahedral silicate layers and octahedral MgO_6 layers. This is consistent, but not exclusively,

452   with the presence of a kerolite and/or stevensite phase. However, this large band at 1020-1026

453   cm^{-1} is not observed in 1:1 layered configuration silicates such as serpentines, which are

454   mainly characterized by 2 bands around 990 et 1080 cm^{-1} (Yariv and Heller-Kallai, 1975).

455   FTIR spectra of all four microbialites also showed one peak at 3679-3681 cm^{-1}, interpreted as

456   a Mg$_3$-OH stretching band, characteristic of Mg in octahedral coordination, consistent but not

457   exclusively with kerolite/stevensite (Fig. 6b; Tosca et al., 2011). Additional bands at 3624 and

458   3647 cm^{-1} in the Pátzcuaro microbialite may result from a splitting of the hydroxyl stretching

459   in kerolite due to the substitution of Mg by Fe (Fig. 6b; Wilkins and Ito, 1967). Again, these

460   bands are significantly different from those observed in 1:1 layered configuration silicates

461   such as serpentines, which appear at 3652, 3669, 3688 and 3703 cm^{-1} for lizardite (Trittschack

462   et al., 2012) or 3644 and 3689 cm^{-1} in chrysotile (Bishop et al., 2002). Last but not least, the

463   $\nu_3 CO_3$ band at 1384-1385 cm^{-1} was detected in La Preciosa, Atexcac, La Alberca de Los

464   Espinos and Pátzcuaro (Fig. 6 a-c). While this band may be due to LDH and/or aragonite in

465   ATX-2C1-2012, Preciosa05-2012, and Patz2014-02, it was likely associated with LDH in

466   AlbEsp2014-02 since no other band characteristics of aragonite was observed in this sample.

467

468   **3.3. Microscopy analyses of Fe-bearing phases**

469   Fe-rich areas were observed by microscopy in all the samples except the La Preciosa

470   microbialite. Light and scanning electron microscopies as well as μ-XRF analyses showed

471   that Fe distribution in microbialites was discrete, with the existence of Fe-hotspots (Figs. 7

472   and 8). In AL2014-15, Fe was contained in numerous thin laminae, measuring less than 10

473   μm in thickness as well as patches of ~100 μm in width (Fig. 7 a-b). Fe-rich phases

474   sometimes appeared extinct under cross polars as observed for AL2014-15 suggesting the

475   presence of a poorly crystalline phase. In AL13, Fe hotspots appeared as laminae and patches

476   beneath an aragonite layer located at the surface of microbialites (Fig. 7 c-d). In ATX-2C1-

477   2012 and Patz2014-02, Fe phases were distributed as ~50-200 μm thick laminae (Fig. 7 e-f-g-

478   h).

479

3.3.1. Fe-bearing phases in Alchichica microbialites

Synchrotron-based μ-XRF maps showed that Fe in AL66 was concentrated in discrete laminae, beneath an aragonite layer located at the surface of microbialites (Fig. 8 a-b). The same Fe-rich areas were analyzed at a higher spatial resolution by SEM-EDXS. These Fe laminae showed a smooth texture and were sandwiched between a surface layer of aragonite and an inner mass of hydromagnesite (Fig. 8). One FIB foil was cut across a Fe-rich lamina (Fig. 8c) and analyzed by TEM. At the nanoscale, one phase with a fibrous texture appeared to bear Fe together with Mg and Cl and almost no Al (Fig. 9 a-b-e area#1). The selected area electron diffraction (SAED) pattern of this phase showed diffuse spots with d-spacings at 2.65, 2.43 and 1.55 Å corresponding to the (101), (0-11) and (-1-10) lattice planes, respectively, viewed along the [1-1-1] zone axis of a LDH phase (Fig. 9c). In accordance with bulk XAS analyses, this phase was interpreted as a Mg-, Fe-, and Cl-rich LDH phase, i.e. iowaite ($Mg_6Fe(III)_2(OH)_{16}Cl_2 \cdot 4H_2O$). Iowaite was overlain by crystalline micritic aragonite as attested by EDXS and SAED analyses (Figs. 9 a-b-d-e area#2 and SI-7).

Similar as in AL66, Fe-rich areas in AL13 also appeared between a surface aragonite layer and an inner mass of hydromagnesite forming the bulk of the microbialite (Fig. 10). Some Fe-rich laminae were also detected within the aragonite layer and a FIB foil was cut across one of them (Fig. 10c). The Fe-rich lamina sampled in the FIB foil measured ~1 μm in width. It was smooth and darker than the surrounding aragonite by STEM-HAADF (Fig. 11). This lamina was mostly composed of Mg, Cl and Fe, similarly to iowaite in AL66 with minor amounts of Si and Al. However, the rings in the SAED pattern were much more diffuse so that d-spacings could not be determined (Fig. 11d). Fe in this phase was mostly in the form of Fe(III) as shown by the prominent peak at 710.3 eV in the XANES spectrum measured by STXM at the Fe $L_{2,3}$-edges (Fig. 11g). This agreed with bulk XAS measurements. Finally, this

504 Fe-rich lamina contained organic matter as attested by STXM analyses at the C K-edge (Fig.

505 11 h-i). Indeed, XANES spectra measured on the lamina showed peaks at 1) 284.9 eV,

506 interpreted as carbon 1s→π* electronic transitions in aromatic and/or olefinic groups (C=C);

507 2) 286.6 eV, interpreted as carbon 1s→π* electronic transitions in ketone/phenol group

508 (C=O); 3) 287.3 eV, interpreted as carbon 1 s→σ* transitions in aliphatic groups and 4) 288.5

509 eV, interpreted as carbon 1s→π* transitions in carboxylic functional groups (Fig. 11i,

510 Benzerara et al., 2004; Bernard et al., 2010). An additional peak at 290.3 eV was interpreted

511 as carbonate C (Benzerara et al., 2004), suggesting that in addition to iowaite, there was also a

512 CO_3-containing LDH phase, i.e. pyroaurite ($Mg_6Fe(III)_2(OH)_{16}CO_3 \cdot 4H_2O$), in accordance

513 with FTIR analyses.

514 AL2014-15 contained a much higher Fe content than AL13 and AL66. Consistently,

515 large Fe-rich areas were observed by light microscopy and SEM (Figs. 7 a-b and 12). A FIB

516 foil was cut within one of these areas, across two Mg- and Fe-rich, Si-poor objects with

517 circular cross-sections surrounded by a Fe- and Si-rich mineral matrix (Fig. 12). TEM

518 analyses showed three different mineral phases with different textures in the FIB foil (Fig.

519 13): 1) pyroaurite/iowaite, appearing smooth when observed by bright-field TEM and STEM-

520 HAADF and forming bands measuring 200 nm to 1 μm in width and filling partially the

521 objects. This phase was composed of Mg, Cl and Fe and showed a SAED pattern consistent

522 with pyroaurite/iowaite observed along the [1-1-1] zone axis (Fig. 13a-b-c area#1-d). 2) The

523 second mineral phase was fibrous and corresponded to the matrix surrounding the objects

524 (Fig. 13 a-b-f-g). This phase was composed of Fe with Si and Mg as shown by EDXS

525 analyses with a Fe proportion (X_{Fe}=Fe/(Mg+Fe)) close to 0.7 (Fig. 13 c area#2). Its SAED

526 pattern showed diffuse rings at ~3.15, ~2.55 and ~1.50 Å (Fig. 13 a-e), consistent with

527 phyllosilicates such as the silico-ferric precipitates synthetized at 150°C by Decarreau et al.

528 (1987). The *d*-spacings at 2.55 and 1.50 Å were also compatible with the (110) and (300)

529 planes of ferrihydrite, that may contain high amount of Si (Schwertmann and Cornell, 2000).

530 3) Aragonite appeared as well crystalline micrometer-sized grains in bright-field TEM (Fig.

531 13 f-h).

532

533 **3.3.2. Fe-bearing phases in Atexcac, La Alberca de Los Espinos and Pátzcuaro**

534 **microbialites**

535 Although Fe contents in ATX-2C1-2012, Patz2014-02 and AlbEsp2014-01 were

536 relatively low, some Fe-containing areas could be detected by SEM-EDXS (Fig. 14). In all of

537 them, Fe was systematically associated with Si and Mg (Fig. 14), consistently with bulk XAS,

538 FTIR and XRD analyses that showed Fe incorporation in a talc-like phase. The presence of Fe

539 in a talc-like phase in ATX-2C1-2012 microbialite sample was also supported by previous

540 electron microprobe analyses showing (Mg+Fe)/Si ratio equal to 0.82 ± 0.06 (Zeyen et al.,

541 2015). Moreover, most of the occurrences that we observed were Al-poor except for

542 Patz2014-02 (Fig. 14 d-e-f). FIB foils were cut within two distinct Fe-rich areas in ATX-2C1-

543 2012: one was analyzed by Zeyen et al. (2015); one has been characterized by TEM and

544 STXM in the present study (Figs. 15 and 16). This FIB foil contained two mineral phases: 1)

545 aragonite which appeared as aggregated crystalline grains measuring few hundreds of

546 nanometers, with a high diffraction contrast in bright field TEM, and a bright contrast in

547 STEM-HAADF; 2) the Fe-rich phase with a smooth texture and a darker contrast in STEM-

548 HAADF (Fig. 15 c-d). SAED patterns acquired on the Fe-rich phase showed very diffuse

549 rings attesting that it was poorly crystalline (Fig. 15e). In agreement with SEM observations,

550 STEM-EDXS analyses indicated that this Fe-rich phase contained mostly Si and Mg (Fig.

551 15h). Some Al was also detected here in contrast with SEM analyses and previous TEM

552 analyses on Fe- and Mg-rich silicates reported by Zeyen et al. (2015). XANES spectroscopy

553 at the Fe $L_{2,3}$-edges indicated that Fe was mostly in the form of Fe(III) in this phase (Fig. 16

554 a-b). Again, this Fe- and Si-rich phase was associated with organic matter. XANES spectrum

555   at the C K-edge showed the same peaks as observed in the AL13 iowaite/pyroaurite lamina,

556   indicative of aromatic and/or olefinic, ketone/phenol, aliphatic and carboxylic C-functional

557   groups (Fig. 16c). Similarly, a peak located at 290.4 eV was observed and could be

558   interpreted as carbonate C and/or metal-carboxylic C complexes (Chan et al., 2009).

559

560   **4. DISCUSSION**

561

562   **4.1. Origins of the Fe content in Mexican microbialites: authigenesis *vs* detrital input**

563   The Fe content of Mexican microbialites varied between 0.12 wt.% in AL13 and 2.24

564   wt.% in AL2014-15. Depending on the lakes, Fe was found in a variety of mineral phases as

565   summarized in Table 4, including pyroaurite/iowaite, Fe-bearing kerolite/stevensite, a

566   dioctahedral 2:1 phyllosilicate, possibly illite and/or a smectite phase such as nontronite,

567   ferrihydrite and possibly goethite, as inferred by a combination of XANES, XRD, FTIR and

568   electron microscopy. As a comparison, carbonates (specifically analyzed by leaching

569   experiments) within modern marine microbialites from the Heron Reef Formation (Australia)

570   contained lower Fe concentrations, less than 0.005 wt.% (Von Blanckenbourg et al., 2008).

571   The chemically sorted carbonate fraction composing Archaean stromatolites studied by Von

572   Blanckenbourg et al. (2008) from the Strelley Pool Formation (Pilbara craton, Australia), the

573   Mushandike Formation (Masvingo Greenstone Belt, Zimbabwe craton), the Gamohaan,

574   Kogelbeen and the Boomplaas formations (Kaapvaal craton, South Africa) had Fe

575   concentrations ranging from 0.02 to 1.51 wt.%. Proterozoic stromatolites from the 1.89 Ga

576   Gunflint and Biwabik Fe formations (Animikie basin) studied by Planavsky et al. (2009) had

577   Fe contents varying between 0.02 and 14.11 wt.%, with Fe possibly comprised within

578   hematite, magnetite, siderite and/or ankerite as inferred by XRD and standard petrographic

579   techniques. All of them were interpreted as microbially-mediated authigenic phases. Overall,

Fe contents of the modern Mexican microbialites appeared relatively high, considering that they formed at shallow depth in oxic and alkaline water. Carbonate phases were a negligible carrier of Fe in Mexican microbialites. Instead, Fe was found in discrete laminae between distinct carbonate phases, such as hydromagnesite and aragonite. This suggests that Mexican microbialites formed by alternating periods when Fe-poor carbonates formed and periods when Fe-rich phases formed. Moreover, in Alchichica microbialites, Fe-rich laminae outlined some transition between hydromagnesite and aragonite laminae. Such an association is difficult to explain based on the hypothesis made by Kaźmierczak et al. (2011), who proposed that hydromagnesite forms secondarily as a replacement of aragonite. In contrast, the Holocene hydromagnesite deposits at Atlin (British Columbia, Canada) are mainly composed of hydromagnesite and magnesite, while aragonite is only observed in crack fills suggesting a primary origin for hydromagnesite formed by both abiotic and biotic processes (Stamatakis et al. 2007). In the Kozani Basin, an ancient lacustrine system in Greece, Stamatakis (1995) showed that pCO$_2$ was the key parameter explaining the precipitation of hydromagnesite versus huntite, aragonite and brucite. Similarly, the aragonite-pyroaurite/iowaite-hydromagnesite association in Lake Alchichica may result from some significant hydrochemical variations, which occurred at a certain time in the lake from conditions conducive to hydromagnesite precipitation to conditions favoring aragonite formation through an episode of pyroaurite/iowaite precipitation. Regardless, we note that the environmental message carried by Fe in these microbialites relates to the origin and the fate of oxyhydroxides, silicates and layered double hydroxides and not the carbonate phases (i.e. aragonite, hydromagnesite, calcite or monohydrocalcite).

Some of the Fe-bearing phases may be detrital. In AL13, Preciosa05-2012, ATX-2C1-2012, AlbEsp2014-02 and Patz2014-02, XANES spectra included the contribution of a Fe-bearing dioctahedral 2:1 phyllosilicate. While the XANES spectrum of illite was used a

605   reference endmember for the fitting procedure, no illite was detected by XRD. Instead, this

606   Fe-bearing dioctahedral 2:1 phyllosilicate might be nontronite, consistent with XRD data

607   measured on Preciosa05-2012 and Patz2014-02 samples (Decarreau et al., 2008). Moreover,

608   the occurrence within microbialites of nontronite, a common alteration product of basalt,

609   would be consistent with the alteration of the surrounding mafic catchment/bedrock (Velde,

610   2003). Alternatively, the broad XRD peaks at 4.5, 2.5 and 1.5 Å may relate to Mg-kerolite

611   and/or stevensite only and not Fe-bearing phases. Microscopy analyses showed some

612   occurrences of mineral phases containing Mg, Fe, Si and Al in ATX-2C1-2012 and Patz2014-

613   02, which could be nontronite. Nevertheless, it should be noticed that a Mg-, Fe- and Si-rich

614   phase with a very similar texture and no Al was also found in ATX-2C1-2012 (Zeyen et al.,

615   2015), suggesting that if a dioctahedral 2:1 phyllosilicate such as nontronite phase may

616   contain some of the Fe, an Al-free phyllosilicate also accommodates some of the Fe.

617   Whatever the identity of the Fe-carrying dioctahedral 2:1 phyllosilicate, several observations

618   suggest that a significant amount of Fe was carried by non-detrital phases in Mexican

619   microbialites. First, no correlation was observed between Fe and the Al, K and Ti bulk

620   contents of the microbialites, as this would be expected from a major detrital input. Moreover,

621   Fe-bearing phases observed by microscopy frequently displayed textures indicative of *in situ*

622   precipitation such as Fe-bearing phases templating objects with circular cross-sections,

623   possibly biogenic structures. Thus, authigenesis scenarios are provided hereafter for the

624   formation of Fe-bearing kerolite/stevensite-like and pyroaurite/iowaite phases, two of the

625   main Fe-bearing phases detected in the microbialites.

626

627   **4.2. Fe-bearing layered double hydroxides in Alchichica microbialites**

628   In Alchichica microbialites, part and sometimes most of Fe was borne by layered

629   double hydroxides (LDH), sometimes referred to as hydrotalcite (Hall and Stamatakis, 2000),

630   a mineral supergroup comprising more than 40 naturally-occurring mineral species with a

631   layered double hydroxide structure (Mills et al., 2012). LDH structure consists of positively

632   charged brucite-type layers ($Mg(OH)_2$) separated by intercalated, charge balancing anions

633   (Schutz and Biloen, 1987). Chemical compositions of LDH widely vary (Allada et al., 2006)

634   in terms of their divalent cation content (e.g., Mn(II), Mg(II), Ni(II)), their trivalent cation

635   content (e.g., Al(III), Fe(III), Cr(III)) and the interlayer anions (e.g., CO_3^{2-}, NO_3^-, Cl^-, SO_4^{2-}).

636   Here, XANES, FTIR, STXM and TEM analyses showed that the LDH phase in Alchichica

637   microbialites contained chloride and carbonates as interlayer anions, Mg as a divalent cation

638   and Fe(III) as a trivalent cation. Therefore, this phase belongs to the iowaite

639   ($Mg_6Fe(III)_2(OH)_{16}Cl_2 \cdot 4H_2O$) – pyroaurite ($Mg_6Fe(III)_2(OH)_{16}CO_3 \cdot 4H_2O$) group.

640   A carbonate-bearing LDH phase was also detected by FTIR in microbialites from La

641   Preciosa, Atexcac, La Alberca de Los Espinos and Pátzcuaro. However, XAS and electron

642   microscopy analyses suggested that this phase was not a significant carrier of Fe in these

643   microbialites, either because this phase was hydrotalcite *sensu stricto*, i.e. it contained Al(III)

644   instead of Fe(III) as a trivalent cation and/or because iowaite/pyroaurite was rare compared to

645   other Fe-phases.

646   Iowaite was first described in Precambrian serpentinites (Kohls and Roda, 1967).

647   Nonetheless, this alteration phase postdates the formation and its age is not known. Iowaite

648   and pyroaurite are rare minerals but they have been found in abundance in ultramafic deposits

649   (e.g., Kohls and Rodda, 1967; Frost and Erickson, 2004; Bach et al., 2004; Turvey et al.,

650   2017). For example, pyroaurite has been detected as one of the weathering byproducts of

651   serpentinite following infiltration of alkaline (pH>8) groundwater rich in Mg^{2+}, HCO_3^-, SO_4^{2-}

652   and Cl^- (Taylor et al., 1991; Milodowski et al., 2009; Stamatakis and Mitsis, 2013). Pyroaurite

653   is supposed to be late-stage alteration phase forming under oxidizing conditions (Bach et al.,

654   2004). However, based on laboratory experiments, McCollom et al. (2016) suggested that

655   iowaite may precipitate under reducing conditions in some cases. Interestingly, the same

656   mineral assemblage as that observed in Alchichica microbialites, i.e. pyroaurite and/or iowaite

657   together with hydromagnesite, has been classically detected in carbonation products of the

658   ultramafic tailings of the Clinton Creek asbestos mine (Yukon, Canada), the Mount Keith

659   nickel mines (Western Australia) and the Woodsreef tailings (New South Wales, Australia)

660   (Wilson et al., 2014; Power et al., 2014, McCutcheon et al., 2016; Turvey et al., 2017).

661   Moreover, hydrotalcite, manasseite $(Mg_6Al_2(CO_3)(OH)_{16}\cdot4H_2O)$ and pyroaurite were

662   observed in close association with hydromagnesite in heavily sheared serpentinized rocks in

663   Nain Ophiolites (Iran) (Eslami et al., 2015). These authors argued that these Mg- and Fe-rich

664   carbonates were formed by the percolation of Mg-rich meteoric water through serpentinites.

665   Similarly, pyroaurite in association with hydromagnesite have also been observed as

666   secondary alteration byproducts of serpentinites in the ophiolites from the Geraneia

667   Mountains (Greece) due to groundwater circulation of alkaline fluids with a high Mg/Ca ratio

668   (Stamatakis and Mitsis, 2013). Last, LDH (including iowaite) have been highlighted in a

669   context of active serpentinization in hyperalkaline springs in Oman (Chavagnac et al., 2013).

670   Nevertheless, the geodynamic environment in Alchichica is very different, indicating that the

671   paragenesis hydromagnesite/pyroaurite-iowaite can be found in other environments than

672   ultramafic massifs. Indeed, no ultramafic deposit has ever been reported in Alchichica or

673   within the broader Serdan-Oriental Basin, where deposits are invariably basaltic, andesitic or

674   rhyolitic (e.g., Siebe et al., 1995; Zimmer et al., 2010; López-Rojas and Carrasco-Nunez,

675   2015). On the West shore of Lake Alchichica, where we observed the largest LDH contents in

676   microbialites, the nearby basaltic scoria cone is the most likely Fe-rich source explaining the

677   local high enrichment of microbialites in Fe. The high alkalinity of Lake Alchichica, possibly

678   due to microbial activity, together with its low concentration in dissolved H_4SiO_4, possibly

679   due to diatom activity, may explain why overall Lake Alchichica hydrochemistry looks

680   similar to that of fluids in weathered ultramafic settings and therefore why precipitating

681   mineral phases are similar to those found in these environments.

682   In the context of basalt alteration, LDH phases can also form, but in this case the

683   trivalent cation is generally Al(III). The mineral phase hydrotalcite

684   ($Mg_6Al_2(OH)_{16}CO_3 \cdot 4H_2O$) was observed in several experiments altering basalt glass in

685   seawater (Larsen et al., 1991; Thomassin and Touray, 1982; Crovisier et al., 1983a;

686   Abdelouas et al., 1994). For example, basaltic glass experimentally altered at 50°C for 20

687   days was shown to be covered by a layered alteration shell, comprising hydrotalcite between

688   an inner serpentine-type phyllosilicate layer and a saponite layer (Crovisier et al., 1983a).

689   However, it was reported that pyroaurite formed at a lower temperature of 25°C after 240

690   days (Crovisier et al., 1983b). The authors suggested that hydrotalcite formed at 50°C,

691   because at this temperature Fe was poorly mobile and stayed at the base of the alteration shell,

692   while at 25°C, Fe was more mobile and could react with dissolved Mg to precipitate

693   pyroaurite from the solution. The absence of Al in Alchichica LDH phases suggests that they

694   were not formed at the contact of basalts before transport to the microbialites but more likely

695   formed from a solution similar to that prevailing in experiments by Crovisier et al. (1983b).

696   Whatever the geodynamic context, several modes of pyroaurite/iowaite formation

697   have been suggested: these phases can form through a solid-state transformation of Fe(II)-

698   bearing brucite by oxidation of Fe(II) to Fe(III) accompanied by the Cl^- and CO_3^{2-}

699   incorporation between brucite layers (Heling and Schwarz, 1992). Alternatively, Grguric et al.

700   (2001) proposed that iowaite and pyroaurite formed by transformation of magnetite by

701   reaction with alkaline and Cl-rich brines in the Mount Keith nickel deposits. Similarly, Wang

702   et al. (2013) showed the transformation of lepidocrocite and akaganeite into iowaite after their

703   exposure to the salt aerosols of Lake Qinghai. Last, Hansen and Koch (1995) showed that

704   pyroaurite can precipitate from solution following Fe(II) oxidation in Mg-rich, carbonate-

705 and/or Cl⁻-containing solutions at pH>8.5. Here, we have no definitive evidence allowing us

706 to discriminate between these three possibilities for the formation of pyroaurite/iowaite in

707 Lake Alchichica. Nonetheless, in some cases, we observed that iowaite/pyroaurite was

708 contained in biomorphs and was associated with organic matter down to the nm-scale (Figs.

709 11 and 13), suggesting that it may have precipitated from solution in contact with

710 microorganisms. Metagenomic studies of Lake Alchichica microbialites did not evidence 16S

711 rDNA gene sequences indicative of classically known Fe-cycling bacteria, i.e., dissimilatory

712 Fe-reducing bacteria or Fe-oxidizing bacteria (Saghaï et al., 2015 and 2016). However, these

713 studies have shown that microbialites are associated with a large proportion of photosynthetic

714 microorganisms that need Fe as a nutrient. Interestingly, there were significant differences in

715 the local diversity of photosynthetic eukaryotes associated with North *vs* West microbialites.

716 While diatoms dominated the eukaryotic fraction of a microbialite sample from the seepage-

717 influenced West shore of Lake Alchichica, they were marginal in North shore microbialites,

718 where eukaryotes were scarce and dominated by green algae (Saghaï et al., 2015 and 2016).

719 In our study, the microbialite sample from the West shore of Lake Alchichica showed a

720 higher Si concentration (1.02 ± 0.05 wt.%) compared to the microbialite from the North shore

721 (0.65 ± 0.03 wt.%) (Table 2) and was characterized by large areas of Si associated with Fe

722 (Fig. 12). This Si likely came from the groundwater seepage, which has been shown to be

723 more Si-rich (between 13 and 230 times higher) than the Lake Alchichica water (Table 1;,

724 Armienta et al., 2008; Kaźmierczak et al., 2011; Sigala et al., 2017). Future studies

725 documenting the relative contribution of hydrothermalism/underground water to the

726 hydrological budget of the lake will be interesting to address this point. The existence of local

727 seepage rich in H_4SiO_4 on the West shore is also consistent with the local proliferation of

728 diatoms. In turn, diatom abundance implies the increased in situ availability of Si in

729 microbialites from frustule dissolution. Therefore, in addition to the local variation of water

730 chemistry, the differential composition of microbial communities could also explain, at a

731 smaller scale, the different type of minerals observed within microbialites. Microbes could

732 play an important role in the precipitation of Fe-bearing phases by influencing particular

733 concentration of ions (such as Fe or Si). Furthermore, the patchy distribution of Fe in

734 microbialites suggests that Fe-rich conditions might be locally and temporally limited.

735 Finding living microbialites mineralizing under Fe-rich conditions would be useful in order to

736 better understand the potential interactions existing between microorganisms and Fe, their

737 involvement in Fe-rich phase formation and subsequent transformation.

738   Overall, we suggest the following scenario similar to that proposed by Taylor et al.

739 (1991) for the formation of pyroaurite associated with the weathering of partially

740 serpentinised harzburgite in Oman (Fig. 17): (1) basalts around Lake Alchichica, outcropping

741 mostly on the West shore of the lake, were altered by the circulation of groundwater anoxic

742 fluids. Fe(II) but little Al and Si were released into these fluids. (2) When these fluids came

743 into contact with Lake Alchichica water, Fe(II) became oxidized in a Cl^--, Mg^{2+}-, CO_3^{2-}- and

744 O_2-rich solution as well as at high pH (~9) and high alkalinity (~40 mM), favoring

745 pyroaurite/iowaite precipitation. Alternatively, Fe(II) may oxidize and be sequestered as Fe-

746 oxyhydroxides first before secondary transformation into pyroaurite/iowaite following

747 prolonged contact with Lake Alchichica water. Noteworthy, Fe-oxyhydroxides phases such as

748 ferrihydrite have a slightly higher solubility at pH=9 than at pH=7 (Stefánsson, 2007). In

749 addition, the presence of organic molecules may also increase the apparent solubility of Fe by

750 complexation (Kuma et al., 1996), making Fe available for pyroaurite precipitation. Overall,

751 the high Fe content in the microbialites and the presence of iowaite/pyroaurite trace

752 groundwater input to the formation of microbialites.

753

754 **4.3. LDH *vs* silicates**

755   While iowaite/pyroaurite were major carriers of Fe in Alchichica microbialites, these

756   phases were not observed in microbialites from other lakes. Poorly crystalline Fe-bearing talc-

757   like phases were observed instead. An authigenic hydrated and poorly crystalline talc-like

758   phase ($Mg_3Si_4O_{10}(OH)_2 \cdot nH_2O$) similar to kerolite and/or stevensite was detected in Lake

759   Atexcac by Zeyen et al. (2015). Lake Atexcac, Lake La Preciosa, Lake Patzcuaro and Lake

760   La Alberca de Los Espinos were all shown to be supersaturated with regards to Mg-silicates

761   (Zeyen et al., 2017), which supports the possibility that such a phase precipitates in these

762   lakes. Moreover, it was shown by microscopy that this phase sometimes contains Fe in Lake

763   Atexcac, in agreement with the possibility that Fe(II) substitutes for Mg(II) and Fe(III)

764   substitutes for Mg(II) (with the loss of a proton) and/or Si in the structure of nanocrystalline

765   2:1 trioctahedral phyllosilicates such as kerolite and/or stevensite (Forbes, 1969; Corona et

766   al., 2015).

767   It is important to note that the majority of Fe was in the form of Fe(III) in all Mexican

768   microbialites. Fe may have been incorporated as Fe(II) in kerolite and/or stevensite before

769   later solid-state oxidation at the contact with oxic water. This is consistent with the fact that

770   EXAFS results on our model compounds suggest that the nano-Fe(III):talc component

771   identified in the XANES spectrum of the Preciosa05-2012, AlbEsp2014-01, ATX-2C1-2012

772   and Patz2014-02 microbialite samples can be interpreted as a byproduct of the oxidation of a

773   nano-Fe(II)-talc component (Fig. SI-5). In the present study, we extend the record of such Fe-

774   bearing talc phases to Lake La Alberca de Los Espinos and Lake Pátzcuaro. Following what

775   was observed in Lake Alchichica, we proposed that Fe-enrichments may also be due to

776   seepage in these volcanic lakes bringing Fe(II)-rich fluids to oxic water.

777   The reason why Fe was incorporated into pyroaurite/iowaite in Lake Alchichica *vs*

778   kerolite/stevensite in other lakes, despite similar total Fe contents, might be related to the

779   differences in chemical conditions prevailing in these lakes. Although the formation of

780   pyroaurite/hydrotalcite may require relatively higher pH than a silicate phase (e.g., Besson et

781   al., 1974; Miyata and Okada, 1977; Crovisier et al., 1983b), this may not be a major

782   parameter here since all studied lakes had similar pH values 8.5-9 (Zeyen et al., 2017). In

783   contrast, H_4SiO_4 concentrations were much lower in Lake Alchichica ([H_4SiO_4]= 0.017 mM;

784   Kaźmierczak et al., 2011) compared to the other lakes which showed orthosilicic acid

785   concentrations higher than 0.37 mM and up to 1.0 mM in Lake Atexcac (Zeyen et al., 2015 &

786   2017). Chavagnac et al. (2013) argued that the chemical composition of the solution,

787   specifically its H_4SiO_4 concentration, is of essential importance in controlling the type of clay

788   (cationic or anionic) formed. These authors detected LDH, including iowaite, in a springwater

789   with a low H_4SiO_4 content (<10 μM) and a high pH (12). Interestingly, previous experimental

790   studies of basaltic glass alteration have shown that hydrotalcite can transform into an Al-

791   bearing serpentine and/or a smectite-like Fe-Mg-rich phase following reaction of the

792   hydrotalcite precursor with orthosilicic acid accumulating at an increasing concentration in

793   the solution (Thomassin and Touray, 1982; Crovisier et al., 1983a; Abdelouas et al., 1994).

794   This hydrotalcite to silicate transformation has been suggested to occur through

795   dissolution/precipitation in the presence of dissolved orthosilicic acid (Besson et al. 1974).

796   Overall, LDH may form and stay preserved in Lake Alchichica because of the low [H_4SiO_4]

797   prevailing in this lake, while in other lakes, Fe-bearing kerolite or smectite phases form from

798   the transformation of a transient iowaite/pyroaurite phase or direct precipitation. Future

799   synthesis experiments will be necessary to better constrain chemical parameters (e.g.,

800   [H_4SiO_4], alkalinity) favoring silicates versus LDH-like phases within microbialites.

801

802   **5. CONCLUSION**

803

804   Microbialites from Mexican alkaline crater lakes sometimes contain high Fe contents.

805   A large part of Fe is in the form of Fe(III). Part of Fe is mineralized in authigenic phases, i.e.

806   iowaite/pyroaurite in Lake Alchichica and Fe-bearing kerolite and/or stevensite in lakes La

807   Preciosa, Atexcac, Pátzcuaro and La Alberca de Los Espinos. These Fe-bearing phases are

808   distributed along discrete thin laminae as well as large Fe-rich areas within microbialites.

809   The concentration of orthosilicic acid in the lakes seems to be a major parameter

810   controlling the nature of the Fe-bearing phases that form. To our knowledge, layered double

811   hydroxide (LDH) phases such as iowaite/pyroaurite phases have never been reported before in

812   ancient or modern microbialites. This might be due to 1) the specific chemical conditions

813   required for their formation, e.g. high alkalinity, $[CO_3^{2-}]$, pH, $[Cl^-]$ and $[Mg^{2+}]$ combined with

814   low $[H_4SiO_4]$; 2) the difficulty in detecting and characterizing these phases, especially when

815   there are in low abundance; 3) the reactivity of these phases to silica, leading to potentially

816   poor preservation in the geological record; 4) the presence of specific microbial communities

817   locally modifying ion concentrations and pH.

818   While the Fe-bearing phases in modern microbialites may carry some information on

819   their formation conditions, their fate in the geological record remains unknown. In these

820   Mexican lakes, the LDH phases appear to sometimes be finely associated with organic matter.

821   How their formation and reactivity interfere with microbial communities populating the

822   surface of these microbialites and to which extent these phases are implicated in the

823   fossilization processes of microorganisms will deserve further attention. Furthermore, the

824   precise range of geochemical conditions allowing pyroaurite-iowaite formation and the

825   stability of LDH through geological time will need to be determine in the future. To our

826   knowledge, no study exists on the fate and transformation of LDH over geological time. We

827   postulate that aging not involving fluids may not modify drastically the mineralogy of these

828   phases. However, late circulations of H_4SiO_4-rich fluids may transform LDH into

829   phyllosilicates as shown by several studies (Crovisier, 1983a, Ford and Spark, 2000). If these

830 transutrmations keep textures intact, the present study offers textural examples of what should

831 be looked for as remnants of LDH within ancient microbialites. In any case, the present study

832 highlights the diversity of the mineral phases bearing Fe in modern environments. This calls

833 for a careful reappraisal of the primary Fe-bearing phases in ancient microbialites so that

834 meaningful paleoenvironmental interpretations can be retrieved from e.g. Fe isotope

835 measurements.

Figure 1.

XANES spectra at the Fe K-edge of AL2014-15, AL66 and AL13 microbialites from Lake Alchichica. (**a**) Spectra of references (goethite, ferrihydrite, hydrotalcite, illite and nano-Fe(II):talc) are shown in colors. Spectra of the microbialites (black lines) are superimposed on fits (red lines) obtained by LC-LSF analysis. (**b**) Proportion of the fitting components: Fe(III):hydrotalcite as a proxy for pyroaurite/iowaite, goethite and ferrihydrite as proxies for Fe (oxyhydr)oxides, nano-Fe(II): and nano-Fe(III):talc as proxies for nanocrystalline 2:1 trioctahedral phyllosilicates, Fe(III)-bearing illite as proxy for 2:1 dioctahedral phyllosilicates.

Figure 2.

Powder X-ray diffraction patterns of Alchichica microbialite samples. (**a**) AL2014-15, AL66 and AL13 microbialite samples. Aragonite (A), hydromagnesite (H) and layered double hydroxide (LDH) were detected. (**b-c**) Close-ups on the LDH peaks at 7.59 Å (13.4° 2Θ) and 3.79 Å (27.3° 2Θ) observed in the pattern of AL2014-15, outlined by red rectangles.

Figure 3.

FTIR analyses of Alchichica microbialites. (**a**) FTIR spectra of AL2014-15, AL66 and AL13 between 400 and 1800 cm^{-1}. Labels are as follows: aragonite (A), hydromagnesite (H) and layered double hydroxide (LDH). (**b**) FTIR spectra from 3000 to 4000 cm^{-1}. (**c**) Close-up of the band at 1384.5 cm^{-1} for AL66 and AL13, interpreted as a carbonate asymmetric stretching mode (v_3CO_3) in LDH or aragonite.

Figure 4.

1176   XANES spectra at the Fe K-edge of microbialites from La Preciosa, Atexcac, La Alberca de

1177   Los Espinos and Pátzcuaro. (**a**). Spectra of the microbialites (black lines) are superimposed on

1178   fits (red lines) obtained by LC-LSF analysis (**b**) Proportion of the fitting components: nano-

1179   Fe(II):talc and nano-Fe(III):talc as proxies for nanocrystalline 2:1 trioctahedral phyllosilicate,

1180   and Fe(III):illite as proxy for 2:1 dioctahedral phyllosilicate.

1181

1182   **Figure 5.**

1183   Powder X-ray diffraction patterns of microbialites from Lakes La Preciosa, Atexcac, La

1184   Alberca de Los Espinos and Pátzcuaro. Aragonite (A), calcite (C), monohydrocalcite (MC),

1185   hydromagnesite (H) and kerolite/stevensite (K/S) were detected.

1186

1187   **Figure 6.**

1188   FTIR spectra of microbialites from Lakes La Preciosa, Atexcac, La Alberca de Los Espinos

1189   and Pátzcuaro. (**a**) Spectra from 400 to 1800 cm^{-1} (**b**) Spectra from 3000 to 4000 cm^{-1}. (**c**)

1190   Close-up of the spectral area between 1372 and 1395 cm^{-1}. The peak at 1384.5 cm^{-1} indicated

1191   by a dashed line was assigned to carbonate asymmetric stretching in LDH and/or aragonite.

1192   Peak labels are as follows: aragonite (A); calcite (C); monohydrocalcite (MC);

1193   hydromagnesite (H); layered double hydroxide (LDH) and kerolite/stevensite (K/S).

1194

1195   **Figure 7.**

1196   Light microscopy observations of Fe spatial distribution in the microbialites. (**a-b**) Plane- and

1197   cross-polarized light photomicrographs of AL2014-15 sample showing dense masses and Fe-

1198   rich fine discrete laminae (arrows). (**c-d**) Plane- and cross-polarized light photomicrographs

1199   of AL13 showing layers of a brownish Fe-bearing phase between aragonite (A) and

1200   hydromagnesite (H) as well within hydromagnesite (white dashed arrow). (**e-f**) Plane- and

1201   cross-polarized light photomicrographs of ATX-2C1-2012 showing a beige Fe-bearing phase

1202   forming a ~20 to 100 μm thick layer at the surface of the microbialite. This phase shows total

1203   extinction under cross-polarized light. (**g-h**) Plane- and cross-polarized light

1204   photomicrographs of Patz2014-02 showing brown Fe-bearing laminae measuring ~50 to 150

1205   μm in thickness (white arrow) and showing extinction under cross polars. A darker Fe-rich

1206   area is also observed (white dashed arrow).

1207

1208   **Figure 8.**

1209   Analysis of Fe distribution in AL66 by correlative electron/x-ray microscopy. (**a**) SEM image

1210   acquired in the BSE (backscattered electron) mode. Labels are as follows: aragonite (A) and

1211   hydromagnesite (H). (**b**) μ-XRF mapping of Fe (red) and Ca (green) in AL66 in the area

1212   outlined by a dashed rectangle in (a). (**c**) SEM image in backscattered electron mode of the

1213   area outlined by a rectangle in (b). Resin appears on the left. Aragonite (A) and

1214   hydromagnesite (H) are separated by a Fe-rich phase showing a darker contrast compared to

1215   aragonite due to the presence of lighter element(s). The red rectangle indicates the localization

1216   of the FIB section cutting across a Fe-rich lamina. (**d**) Overlay of the Fe (red), Mg (blue) and

1217   Ca (green) SEM-EDXS maps. The Fe-rich phase appears in pink (i.e. a combination of Fe and

1218   Mg).

1219

1220   **Figure 9.**

1221   Transmission electron microscopy analyses of a FIB foil cut across aragonite and the Fe-rich

1222   phase in AL66, outlined in Fig. 8c. (**a**) STEM-HAADF image of the FIB foil. (**b**) STEM-

1223   EDXS map of Fe (red), Mg (blue) and Ca (green) of the same area. The Fe-rich phase appears

1224   in pink (i.e. a combination of Fe and Mg). (**c**) Selected area electron diffraction (SAED)

1225   pattern of the circled area #1 on Fig. 9b. Diffuse diffraction spots and arcs were indexed as

1226   lattice planes of LDH and aragonite (A), as indicated on the pattern. (**d**) SAED pattern of

1227   aragonite (area #2 as indicated on Fig. 9b). Radial intensity profile is shown in Fig. SI-7. (**e**)

1228   EDXS spectra of the circled areas noted (1) and (2) on Fig. 9b, corresponding to the Fe-rich

1229   area (composed by Fe, Mg and Cl) and aragonite, respectively (Cu peaks were emitted by the

1230   Cu grid to which the FIB foil was attached).

1231

1232   **Figure 10.**

1233   Analysis of Fe distribution in AL13 by correlative electron/x-ray microscopy. (**a**) SEM

1234   backscattered electron image. (**b**) μ-XRF mapping of the area outlined by a rectangle in Fig.

1235   10a. Fe and Ca are shown in red and green, respectively. (**c**) SEM backscattered electron

1236   image of the area outlined by a rectangle in Fig. 10b. The red rectangle indicates the

1237   localization of the FIB section cutting across a Fe-rich lamina. (**d**) SEM-EDXS map of the

1238   same area showing Fe, Mg and Ca in red, blue and green, respectively.

1239

1240   **Figure 11.**

1241   Transmission electron microscopy analyses of a FIB foil extracted from AL13 (see rectangle

1242   in Fig. 10c). (**a-b**) STEM-HAADF images of the FIB foil. (**c**) STEM-EDXS mapping of the

1243   area outlined by a dashed rectangle in Fig. 11a and showing two distinct mineral phases. Iron,

1244   Ca and Mg are shown in red, green and blue, respectively. (**d**) EDXS spectrum of the area

1245   outlined by a white circle in Fig. 11c. (**e**) SAED pattern of the same area circled in Fig. 11c.

1246   (**f**) STXM Fe map of the FIB foil obtained by subtracting an image at 704 eV (below the Fe

1247 $L_{2,3}$-edges) from an image at 709.7 eV (above the Fe L_3–edge). (**g**) XANES spectrum at the

1248   Fe $L_{2,3}$-edges extracted from the area outlined in Fig. 11f. (**h**) STXM map of two C-bearing

1249   species observed in the area outlined by a dashed rectangle in Fig. 11a, and discriminated

1250   based on their XANES spectra at the C K-edge. Aragonite appears in green, while LDH

1251 appears in red. (**i**) XANES spectrum at the C K-edge of the LDH, observed in red in Fig. 11h.

1252

1253 **Figure 12.**

1254 SEM analysis of the Fe distribution in AL2014-15. (**a**) SEM backscattered electron image.

1255 The red rectangle indicates the localization of the FIB section cutting across two circular

1256 objects. (**b**) SEM-EDXS map of the area outlined by a dashed rectangle in Fig. 12a. Fe, Ca

1257 and Mg are shown in red, green and blue, respectively. Aragonite (A) and hydromagnesite

1258 (H) are surrounding by large Fe- and Si-rich areas. (**c**) SEM-EDXS map of Si corresponding

1259 to the area outlined in Fig. 12a.

1260

1261 **Figure 13.**

1262 TEM analyses of a FIB foil extracted from AL2014-15 as outlined in Fig. 12a. (**a**) Bright-

1263 field TEM image showing an object with a circular cross-section. (**b**) STEM-HAADF image

1264 of the object showed in Fig. 13a. (**c**) EDXS spectra of areas #1 and # 2, outlined in Fig. 13b.

1265 (**d**) SAED pattern of area outlined in Fig. 13a corresponding to area #1: LDH viewed along

1266 the [1-1-1] zone axis. The *d*-spacings at 2.66 Å, 1.55 Å and 1.30 Å corresponded to LDH (-

1267 10-1), (-1-10) and (-20-2) lattice planes. (**e**) SAED pattern of area outlined in Fig. 13a

1268 corresponding to area #2: silico-ferric precipitate as synthesized by Decarreau et al. (1987)

1269 and/or ferrihydrite. *D*-spacings at 3.15, 2.36 and 1.49 Å are identified. (**f**) Bright-field TEM

1270 image of the second object with a circular cross-section. (**g**) Close-up of the fibrous layer

1271 surrounding the object structures as outlined by a dashed rectangle in Fig. 13f. (**h**) SAED

1272 pattern of area 3 circled in Fig. 13f: aragonite with *d*-spacings at 2.48, 1.87, 1.25, 1.12 Å.

1273

1274 **Figure 14.**

1275 SEM observations of Fe-bearing silicates in ATX-2C1-2012, AlbEsp2014-01 and Patz2014-

1276 02. (**a-b-c**) SEM backscattered electron images. (**d-e-f**) EDXS spectra of the areas outlined by

1277 a circle in SEM images. Platinum (Pt) was used to sputter-coat AlbEsp2014-01.

1278

1279 **Figure 15.**

1280 SEM and TEM analyses of ATX-2C1-2012. (**a**) SEM backscattered electron image. (**b**) SEM-

1281 EDXS map of the area outlined in (a). Fe and Ca are shown in red and green, respectively. (**c**)

1282 STEM-HAADF image of the FIB foil extracted from the area outlined by a red rectangle in

1283 (a). (**d**) Bright-field TEM image showing the smooth texture of the Fe-rich phase and the

1284 micritic texture of aragonite. (**e**) SAED pattern of the Fe-rich phase, as outlined by a circle in

1285 (d). (**f**) STEM-HAADF close-up of the area outlined in (d). (**g**) STEM-EDXS map of the

1286 same area. Fe, Ca and Mg are shown in red, green and blue. (**h**) EDXS spectrum of the area

1287 circled in (d) and corresponding to the Fe-rich phase.

1288

1289 **Figure 16.**

1290 STXM analyses of a FIB foil extracted from ATX-2C1-2012. (**a**) STXM Fe map obtained by

1291 subtracting an image at 700 eV converted in optical density (below the Fe $L_{2,3}$-edges) from an

1292 OD-converted image taken at 710 eV. (**b**) XANES spectrum at the Fe $L_{2,3}$-edges of the Fe-

1293 rich area outlined by a white circle in (a). (**c**) XANES spectrum at the C K-edge of the Fe-rich

1294 area outlined by an orange circle in (a).

1295

1296 **Figure 17.**

1297 Schematic diagram suggesting the origin of pyroaurite precipitation in Lake Alchichica. (1)

1298 Basalt alteration by groundwater, releasing Fe(II) (2) Fast oxidation of Fe(II) at the contact

1299 with lake water, rich in Cl^-, Mg^{2+}, and CO_3^{2-} and showing a high pH resulting in

1300 pyroaurite/iowaite precipitation (3).

Table

Table 1.
Summary of the main physical and geochemical parameters of the lakes

Lakes	Predominant ions	Conductivity (mS/cm)	pH	Alk (mM)	Mg (mM)	Cl (mM)	H_4SiO_4 (mM)	Ca (mM)	References

Table 3

Table 3.

Result of the best fits of the Fe K-edge XANES spectra of the microbialite samples, expressed as the relative proportion of the model compounds components. The quality of the LCF fits was estimated by a reduced chi-square parameter $\chi^2_R = n / (n-p) \ \Sigma \ [\mu_{exp} - \mu_{calc}]^2$ where p is the number of fitting components and n is the number of independent parameters corresponding to the energy range divided by the natural width of the U LIII or Fe K levels reported by Krause and Oliver (1979). Figures between brackets indicate 2σ confidence intervals (2*standard deviation).
