Synthesis of Carbon–Nitrogen–Phosphorous Materials with an Unprecedented High Amount of Phosphorous toward an Efficient Fire-Retardant Material

Wenyao Zhang, Jesús Barrio, Christel Gervais, Andraž Kocjan, Aiping Yu, Xin Wang,* and Menny Shalom*

Abstract: Phosphorus incorporation into carbon can greatly modify its chemical, electronic, and thermal stability properties. To date this has been limited to low levels of phosphorus. Now a simple, large-scale synthesis of carbon–nitrogen–phosphorus (CNP) materials is reported with tunable elemental composition, leading to excellent thermal stability to oxidation and fire-retardant properties. The synthesis consists of using monomers that are liquid at high temperatures as the reaction precursors. The molten-state stage leads to good monomer miscibility and enhanced reactivity at high temperatures and formation of CNP materials with up to 32 wt % phosphorus incorporation. The CNP composition and fire-retardant properties can be tuned by modifying the starting monomers ratio and the final calcination temperature. The CNP materials demonstrate great resistance to oxidation and excellent fire-retardant properties, with up to 90 % of the materials preserved upon heating to 800 °C in air.

Carbon materials are widely used for a range of applications such as batteries, supercapacitors, fuel cells, heterogeneous

catalysis, sensors, water treatment, among others.^[1] Insertion of heteroatoms with a different electronegativity into the carbon network can dramatically alter its electronic,^[2] magnetic,^[3] optical,^[4] and electrochemical properties^[5] along with its chemical reactivity.^[6] For example, several studies have shown that the introduction of nitrogen and phosphorus as electron donors into a carbon structure alters its electronic states,^[7] (electro)catalytic properties^[8] and its chemical stability to both oxidation and exposition to high temperatures.^[9] More specifically, doping a carbon matrix with phosphorus significantly enhances its thermal stability^[10] and its electrical conductivity.^[11]

The covalent radius of nitrogen permits its facile incorporation into carbon materials; structures with up to 70 % nitrogen are easily synthesized.^[12] In contrast, the large covalent radius of phosphorus strongly impedes its insertion into the carbon matrix. During the traditional solid-state synthesis of carbon materials, the carbon and nitrogen atoms can build a uniform network which is energetically favorable, whereas the phosphorus is mainly bonded to oxygen and carbon atoms on the surface.^[7b,13] Furthermore, in materials based on carbon and nitrogen, the phosphorus is seldom bonded to nitrogen atoms. Therefore, up to now, only carbon materials doped with low amounts of phosphorus have been prepared and the presence of P–N bonds within the carbon structure has rarely been reported.^[7b,14] Its presence within a carbon network can strongly enhance its chemical and thermal stability,^[15] as well as its electronic and catalytic properties.^[16] Polyphosphazenes are polymers with a P–N backbone, which are usually prepared from poly(dichlorophosphazene). The synthesis of the latter usually requires a highly inert environment and involves the use of catalysts to avoid crosslinking.^[17]

Herein, we report the simple and large-scale synthesis of carbon–nitrogen–phosphorus materials with a large amount of heteroatoms incorporation and up to 32 wt % phosphorus in the final materials. The new materials were obtained by the calcination of mixtures of two monomers, namely hexachlorophosphazene (abbreviated as PNCl) and 2,4-diamino-6-phenyl-1,3,5-triazine (DPT), which form a uniform liquid solution at high temperatures (250–400 °C). The liquid state facilitates the ring-opening of PNCl to poly(dichlorophosphazene), followed by their reaction with amines groups in DPT. Subsequently, upon condensation at high temperatures, a range of new carbon–nitrogen–phosphorus materials are formed; their properties can be tuned by changing the initial monomers composition and the final reaction temperature.

The synthetic route, intermediates, and final materials structure were thoroughly studied by a wide range of techniques. The optimal nanocomposites demonstrate very high stability to oxidation and act as efficient fire-retardant materials.

The carbon–nitrogen–phosphorus materials were synthesized through a reaction involving a molten-state step and a final solid-state condensation as shown in Figure 1 a. Briefly, DPT and PNCl powders in various molar ratios (6:1, 3:1, 1:1, 1:3 and 1:6) were ground into a homogeneous solid mixture. Afterward, the mixture was transferred into a ceramic crucible and heated to 260 °C for 2 h, followed by its calcination under nitrogen atmosphere for another 2 h at a designated target temperature (450, 550, 650, 750, 850 °C). The obtained composites were labeled as D_xPN_y-T ($x:y$ denotes the molar ratio of DPT to PNCl, T denotes the target temperature of the reaction). The reaction yields are given in the Supporting Information, Table S1. The molten-state step allows to shape the final structure as exemplified in Figure 1 a. The cylinder shape can be prepared by preforming the reaction in a glass-tube. The confined reaction vessel together with polyphosphazene structure lead to the formation of CNP monolith.

X-ray photoelectron spectroscopy (XPS) measurements show the typical evolution of the chemical states of P, C, and N for all samples. The P 2p spectrum reveals four phosphorus environments (Figure 1 b). Two dominant species, attributed to the terminal and bridging P environments from the backbone of $-[PNR]_n-$ polymer chains, appeared in all samples. Importantly, the increase of DPT in the precursor mixture led to a small shift of P 2p to lower binding energies. This shift is due to the electron-donating substituents, from the branched phenyl-modified carbon nitride ($Ph-CN_x$) that

is covalently bonded to the PN chain. Additionally, the spectrum for D_6PN_1-550 showed two shoulder peaks, attributed to P 2p_{3/2} and P 2p_{1/2}, at lower binding energies, which correspond to the ternary P atoms from PN chain end-groups. This suggests that at high DPT amount mainly $Ph-CN_x$ is formed and the polymerization with PNCl is inhibited. Consequently, in the final structure, the result of PNCl condensation mostly consists of PN oligomers. The detailed reaction paths and the effect of monomers ratio are discussed below.

C 1s and N 1s XPS measurements show the evolution of CN heterocycles (C and N atoms in $C-N=C$ and $N-(C)_3$ species) at high amounts of DPT in the starting materials reflecting the $Ph-CN_x$ formation. The substitution of PN structure with $Ph-CN_x$ was further supported by X-ray diffraction (XRD) measurements,^[26] Fourier transform infrared (FTIR) spectroscopy, and elemental analysis (EA) data. The XRD patterns (Supporting Information, Figure S1a) reveal that increasing the relative amount of DPT results in the formation of more organized layered structure, as witnessed by the typical stacking peak of carbon nitride gradually appearing and shifting to higher angles, at around 27.5°. The FTIR spectrum of D_1PN_6-550 (Supporting Information, Figure S1b) featured strong and broad absorption bands at 1180 cm⁻¹ and 874 cm⁻¹, corresponding to stretching $P=N^{[18]}$ and $P-N$ vibrations,^[19] respectively. For materials prepared with a larger relative amount of DPT, the typical peaks corresponding to i) the breathing vibration mode of tri-s-triazine subunits at 810 cm⁻¹ and ii) vibrations of aromatic C–N heterocycles at 1200–1600 cm⁻¹ were detected. EA measurements (Supporting Information, Table S2, Table S4) show that the starting monomers ratio is directly related to the relative amounts of elements in the final materials: the relative increase in DPT resulted in more C, N and less P, Cl in the final materials and vice versa. The C/N atomic ratio approached that for $Ph-CN_x$ when using higher DPT/PNCl ratio.

All the above-mentioned measurements suggest that the synthesis involves first the ring opening into linear $-[PNCl]_n-$, followed by its substitution with DPT monomers. Afterward, the attached DPT monomers are further condensed into $Ph-CN_x$. The alteration of the products by the change of the monomers ratio indicates that there is a competition between the DPT condensation and its reaction with the linear PN polymer.

In the next set of experiments, the effect of the final condensation temperature was explored. The thermal properties that are presented later in this manuscript indicate that the D_1PN_3 sample is the most stable to oxidation at high temperature, so we focused on further studying materials of this composition at different calcination temperatures. The C 1s high-resolution XPS spectrum of the D_1PN_3-450 sample confirms the creation of $Ph-CN_x$ phase (Supporting Information, Figure S2) and C–N and C=N bonds were detected. These carbon components show a negligible change upon calcination at 450–650 °C, suggesting that the basic structure of D_1PN_3 was undamaged with increasing temperature. Further increase of the calcination temperature to 750 °C leads to small decomposition of the structure. At 850 °C, most

of the functional groups disappeared and mainly sp^2 carbon was detected, accounting for the collapse of the polymer structure. As reported in heteroatom-doped carbon materials, the dopant atoms incorporate into the π -conjugated system by delocalizing their p-electrons,^[20] this process occurs at 700°C or higher temperatures owing to the formation of thermodynamically stable hybridized carbon. This carbonization process can also be evidenced by the additional new peaks in P 2p and N 1s XPS spectra comparing D₁PN₃-850 samples with the materials that were calcinated at lower temperatures. Apart from XPS, EA and ICP data (Supporting Information, Table S3) were used to demonstrate the variation of the elements ratio at D₁PN₃ with varying calcination temperatures. The EA data shows that up to 750°C, the structure remained almost intact and more than 30 % P was incorporated within the structure. The increase in temperature to 850°C resulted in the loss of most P and only 6 % was detected.

To reveal the reaction mechanism of DPT/PNCl we focused on the elucidation of the synthesis path for the D₁PN₃ sample. A melting point apparatus (MPA), solid-state NMR, scanning electron microscope (SEM), and also thermogravimetric analysis (TGA) and differential thermogravimetry (DTG) were employed to study the growth mechanism, intermediate and final materials. Figure 2a displays photographs of DPT-PNCl mixture (molar ratio of 1:3) in a capillary tube heated at various temperatures in the MPA. Two changes can be observed from the MPA images; first, the solid mixture turned into a quicksand-like mixture at 115°C owing to the melting of PNCl. Afterward, slightly before 260°C the DPT was melted and a transparent homogeneous molten solution was observed. In accordance with the MPA data, TGA and DTG curves (Supporting Information, Figure S3) show that a significant weight loss occurs from 115–200°C due to the monomers phase change, followed by their condensation up to 600°C.

To confirm the critical role of the molten phase, we performed a series of modifications to the reported synthesis. In our experiments, calcination of PNCl alone led to its full decomposition and no material remained after the same synthetic procedure. The importance of choosing two monomers that form a homogeneous molten state is demonstrated by replacing DPT with other nitrogen-rich organic compounds, namely dicyandiamide, melamine, and urea, which are the common precursors to materials based on carbon and nitrogen: none of these monomers exhibit a clear molten phase. When mixed with PNCl and calcinated at high temperatures, they did not form a molten phase: as a result, the PNCl completely evaporated and only carbon-nitrogen materials with a negligible amount of P were formed with non-uniform distribution (Supporting Information, Figures S4, S5).

Solid-state NMR measurements at various reaction temperatures were acquired to elucidate the reaction path as well the intermediates and final materials structure. ¹³C CP MAS spectrum of DPT molecule shows two broad signals centered at 130 and 170 ppm, corresponding to carbon within the phenyl and triazine units, respectively (Figure 3a). A more

precise assignment was obtained from the calculation of ¹³C chemical shift values on the crystalline structure of DPT.^[21] The full chemical shift values assignments are summarized in the Supporting Information, Table S5. Little change is observed in the carbon environments upon the reaction with PNCl at 260°C (1:3 molar ratio of DPT:PNCl) as illustrated by a broadening of the ¹³C signals without significant shifts (Figure 3a.). After heating to 550°C, the ¹³C signals remain in the same chemical shift range and only a significant broadening of the signals was observed, which is probably due to the carbonization of the structure, suggesting the formation of graphitic carbon nitride^[22] and aromatic carbon domains.^[23]

^{31}P MAS spectrum of PNCl shows two narrow signals at 18.8 and 17.6 ppm (Figure 3b) that can be attributed to the two phosphorous inequivalent sites (1:2 ratio) in the crystal-line structure.^[24] After reaction with DPT at 260 °C, the spectrum was drastically changed and broad signals ranging from 10 to -40 ppm appeared. The prominent changes are probably due to the formation of PN_3Cl and PN_4 environments owing to the replacement of Cl group with the NH_2 groups. To further elucidate the P chemical environment, we applied structural modeling (Figure 3c) to calculate the possible ^{31}P chemical shift values (Supporting Information, Table S6) on simple systems with representative phosphorus first neighbors. The absence of signals between 20 and 50 ppm, where peaks for $[\text{PCl}_2\text{N}]_3$ rings would be expected, confirmed the opening of $[\text{PCl}_2\text{N}]_3$ rings.

The formation of P-N bonds leads to phosphorous environments which match our experimental data. Indeed, the calculated chemical shift values for $\text{P}(\text{NP})_x(\text{NH})_{4-x}$ and $\text{P}(\text{NP})_2(\text{NH})\text{Cl}$ cover the whole experimental observed range. This suggests a large distribution of P environments at 550 °C. A more precise assignment would necessitate a much more sophisticated modeling, but it can be noticed that after calcination at 850 °C (Supporting Information, Figure S6) the signal becomes narrower and centered around -3 ppm. This suggests the DPN lost most of its P and turns into carbon, in a good agreement with XPS and EA results.

Having all the data at hand we suggest the following growth mechanism. The heating of PNCl monomer to high temperatures and its interaction with DPT molecules can facilitate and initiate the opening of the cyclic structure to a chain linear polymer. FTIR measurements suggest the formation of a supramolecular assembly that is built from hydrogen bonds interaction between the two monomers at 260 °C (Figure 2b; Supporting Information, Figure S7). The antisymmetric stretching vibration of PN ring was shifted from 783 to 806 cm^{-1} and the stretching vibration of the N-H group in DPT fully disappeared. It is worth noting that the ring-opening reactions usually require the utilization of initiators/catalysts.^[25] Here, the hydrogen bonds network leads to the opening of the ring without any additional catalysts. Subsequently, the chlorine atoms linked to phosphorus are replaced by the active amine groups in DPT as depicted in Figure 2b. At 350 °C, the unreacted amine groups in DPT start to polymerize and establish a scaffold based on carbon and nitrogen. In this case, an ordered carbon-nitrogen structure that substitutes $-\text{[PNR]}_n-$ polymer chains with a well-organized, dense, flat, and smooth morphology (Supporting Information, Figures S8,S9) is obtained from a polymerization in the molten phase at high temperature. The molten phase allows the two monomers to react similarly to the traditional organic chemistry approach owing to the molecules miscibility and reactivity. Therefore, as shown before, it is simple to tune the final elements ratio by adapting the initial monomers ratio. At higher calcination temperatures, the polymerization is followed by a full carbonization of the structure to DPN. Our results indicate that the materials compose from P-N-C bonds.

TGA in air was conducted to evaluate the stability of the new materials to oxidation and their suitability as fire-

retardant materials. First, all the DPNs-550, with DPT:PNCl ratio ranging from 6:1 to 1:6, were analyzed to probe the effect of the elements ratio on the thermal stability (Figure 4a). The T_{10} (the temperature at 10% material loss) strongly depends on the starting and final elements ratio and dramatically increases with higher PNCl amounts (inset in Figure 4a and the Supporting Information, Table S7). The best T_{10} , 747 °C, was obtained for the D_1PN_3 -550 sample. At higher PNCl ratio, a small decrease of T_{10} to 731 °C was obtained. Noticeably, the T_{10} of the carbon-nitrogen scaffold from DPT-550 shows a lower T_{10} value of 574 °C and the material was fully decomposed at about 700 °C. The greater stability of the DPN materials can be attributed to the strong P-N linear backbones within the structure which are known to be stable to oxidation.

We opted to further optimize the best sample (D_1PN_3) by exploring final condensation temperatures from 450 to 850 °C (Figure 4b; Supporting Information, Table S8). The increase of the condensation temperature from 450 to 650 °C results in an increase in T_{10} , up to an impressive 795 °C for D_1PN_3 -650. Further increase in the condensation temperature of the synthesis to 750 °C leads to a slight decrease in T_{10} . The materials synthesized at 850 °C show a similar behavior to the pristine carbon-nitrogen scaffold due to the massive loss of PN units within the structure as shown before. Therefore, based on these results, we conclude that D_1PN_3 -650 exhibits the best stability to oxidation and flame-retardant properties.

The fire-retardant behavior of D₁PN₃-650 was further evaluated by burning it for 30 and 60 min under the hot flame of an alcohol lamp (Figure 4c). Compared with the recent state-of-the-art fire-retardant carbon-based materials,^[10b] our material displays an excellent stability enhancement and only a slight mass loss was obtained (Supporting Information, Figures S10, S11). Images of burned D₁PN₃-650 after soaking it in ethanol are shown in the Supporting Information, Figure S12. Importantly, the sample almost remained intact and the flame did not self-propagate. The FTIR, XPS, and SEM results (Supporting Information, Figures S13–S15) illustrate that the $-\text{[PNR]}_n-$ polymeric chains remain even after 30 min burning, despite some P–O species inevitably appearing. XPS data (Supporting Information, Figure S14) suggests that the carbon was barely oxidized. We proposed that the P is mainly oxidized, protecting the carbon from burning. Recently it was reported that heteroatoms insertion into carbon matrix may lead to the formation of noble carbons with very high resistance to oxidation.^[7d] The chemical stability of D₁PN₃-650 was investigated by immersing it into strong acid and base. The material demonstrated high stability under these harsh condition as shown in Figure S16.

UV/Vis and impedance spectroscopy measurements (Supporting Information, Figure S17) disclose that D₁PN₃-650 is a n-type semiconductor with a band gap of 1.45 eV (Supporting Information, Figure S17). The electric conductivity of D₁PN₃-650 is slightly improved compared to DPT-550 (Supporting Information, Figure S18).

The thermal properties of the D₁PN₃-650 were then evaluated and the corresponding values for effective thermal conductivity (λ_{eff}), diffusivity (κ) and specific heat were $0.157(\pm 0.009) \text{ W m K}^{-1}$, $0.31(\pm 0.05) \text{ mm}^2 \text{ s}^{-1}$, and $0.52(\pm 0.05) \text{ MJ m}^{-3} \text{ K}^{-1}$. It should be mentioned here that both the λ_{eff} and κ are possibly slightly overestimated due to the experimental set-up, where the carbonaceous foam was partially crushed. The low thermal diffusivity can be compared to some polymeric materials, silica or adobe bricks, corroborates well with the observed flame-retardant stability enhancement preventing the excessive propagation of the heat front through the material as displayed in Figure 4c. Analysis of mercury porosimetry shows that the D₁PN₃-650 sample possesses a rather small pore volume ($0.144 \text{ cm}^3 \text{ g}^{-1}$) and a low mesoporosity (only a small fraction of mesopores around 3.5 nm in size), which results the value of λ_{eff} that is not as low as anticipated ($\ll 0.100 \text{ W m K}^{-1}$).

In conclusion, we demonstrate a unique and straightforward approach involving a molten-state step to synthesize CNP materials with unprecedentedly high amount of phosphorus, up to 32 wt %, and controllable elemental composition and chemical properties. To do so, we used two monomers that melt at high temperatures and establish a mixture that is a homogenous liquid up to 400 °C. The molten-state stage leads to excellent monomers miscibility at high temperatures, allowing their reaction as in solution and prevents PNCl evaporation. Detailed structural analysis of the molten-state intermediates and the final carbon–nitrogen–phosphorus materials with various monomers ratio and calcination temperatures reveals that the reaction occurs by the opening of hexachlorophosphazene rings, followed by the

replacement of the chlorine atoms by amine groups of the DPT monomer at the molten-state stage. We demonstrated that the chemical composition and the thermal stability to oxidation at high temperature can be tuned by the starting monomers ratio and the final calcination temperature. Consequently, the materials exhibit great resistance to oxidation and for the best composite up to 90 % of the materials are preserved at 800 °C under air. We believe that the molten-state approach opens the opportunity to overcome some of the traditional solid-state limitations in the synthesis of new materials with controllable and tunable elemental composition as well as variable chemical and electronic properties toward their utilization in fire-retardant materials and electrochemical devices.

Figure 1. a) Illustration of the process for preparing DPN samples involving a molten-state step. b) High-resolution P 2p, C 1s, N 1s XPS spectra of i) D₆PN₁-550, ii) D₃PN₁-550, iii) D₁PN₁-550, iv) D₁PN₃-550, v) D₁PN₆-550.

Figure 3. a) ¹³C CP MAS NMR spectra of i) DPT and reaction products with PNCl (molar ratio of DPT:PNCl of 1:3) at ii) 260°C and iii) 550°C. b) ³¹P MAS NMR spectra of i) PNCl and reaction products with DPT (molar ratio of DPT:PNCl of 1:3) at ii) 260°C, and iii) 550°C. c) Representation of the models I, II, III, and IV obtained through geometry optimization.

Figure 2. a) Melting of the DPT-PNCl precursor seen in the melting point apparatus at controlled temperatures. b) Proposed reaction path of CNP materials.

Figure 4. TGA curves of DPN samples synthesized in a) various raw materials ratio, and b) various calcination temperature measured in air with a heating rate of 10 °C min⁻¹. The insets are the T₁₀ temperatures vs. samples, i) DPT-550, ii) D₆PN₁-550, iii) D₃PN₁-550, iv) D₁PN₁-550, v) D₁PN₃-550, vi) D₁PN₆-550, vii) D₁PN₃-450, viii) D₁PN₃-650, ix) D₁PN₃-750, x) D₁PN₃-850. c) Photographs of the D₁PN₃-650 exposed to a flame (alcohol lamp) after various exposition times.
