Abstract

The corrosion inhibition of nickel in 0.5 M H₂SO₄ by cysteine was investigated with various electrochemical methods and surface observations by SEM. The cyclic voltammetry revealed that the current density is the highest in absence of the cysteine and decreases with increasing inhibitor concentration. The cysteine is an anodic inhibitor. The polarization and electrochemical impedance spectroscopy showed that the cysteine has a poor inhibitive effect. The surface observation by scanning electron microscope corroborates the addition of cysteine has no significant improvement of the surface morphology of nickel electrode in 0.5 M H₂SO₄. Results obtained by different methods corroborate each other.

Keywords: Polarization curves, EIS, Organic Inhibitor, adsorption mechanism.

1. Introduction

Nickel and nickel containing alloys are one of the most important materials for industrial applications. Main properties of nickel are similar to iron. The corrosion of nickel in aqueous electrolytes has been the subject of numerous studies, motivated by the high technological importance of Ni-containing alloys, such as stainless steels and other corrosion resistant alloys [1, 2]. Acid solutions are frequently used for pickling of undesired scale and rust in several industrial processes. Because of its anti-scaling ability, sulphuric acid is widely used to clean the metals and its alloys in various pickling bathes [3]. Although nickel is known as corrosion resistant metal in many aggressive media, it corrodes, nevertheless, at a significant rate in presence of mineral acids or in neutral medium [4].

The use of inhibitors is one of the most efficient methods to mitigate the corrosion of metals. The interaction of metal with inhibitor allows modifying the characteristics of the metal surface and making it more resistant to an aggressive environment. The literature devoting to corrosion inhibition by organic compounds is numerous. The inhibitory action of nickel and its alloys in acidic media by various organic and inorganic inhibitors has been widely studied [5-9].

The most effective organic inhibitors are those compounds containing heteroatoms like nitrogen, oxygen, sulphur and phosphorus [10]. The inhibitory action of these molecules is accompanied by their adsorption on the metal surface. Free electron pairs of heteroatoms i.e. π -electrons, are readily available for sharing to form a bond and act as nucleophile centres of inhibitor molecules. This negative charge facilitates the adsorption process over the metal surface, whose atoms act as electrophile. For instance it was shown that N-containing compounds tend to preferentially adsorb on cathodic sites on iron in acidic solution whereas S-containing compounds mainly function by chemisorption on anodic sites [11-13].

Though many inhibitor compounds showed a good anticorrosive activity, most of them are toxic or harmful to both human beings and environment. The safety and environmental

problems of corrosion inhibitors identified in industries are always a global concern. These toxic or noxious effects lead to the use of ecological and harmless anticorrosive compounds.

Nowadays many alternative eco-friendly corrosion inhibitors are developed; they range from rare earth elements [14-16] to organic compounds [17-20], among others amino acids.

Amino-acids are innocuous, biodegradable, relatively inexpensive and completely soluble in aqueous media. The number of publications about the inhibitory effect of amino acids on corrosion of metals increases [21-25]. In particular, cysteine ($\text{HSCH}_2\text{CHNH}_2\text{COOH}$) stands as one of the most promising candidate. Because this molecule contains the thiol group $[-\text{SH}]$, the amino group $[-\text{NH}_2]$ and the carboxyl group $[-\text{COOH}]$.

This paper focuses on the effect of eco-friendly and innocuous cysteine as nickel corrosion inhibitor in sulphuric acid. We have recently reported the action of cysteine for the corrosion inhibition of copper and cupronickel in 0.5 M H_2SO_4 , and the inhibitory power is found to be remarkable [26]. For this reason, we aimed at to collect the inhibitory performance of cysteine on the corrosion of nickel in 0.5 M H_2SO_4 . This study was carried out by electrochemical methods; evolution of the open circuit corrosion potential, cyclic voltammetry; potentiodynamic polarization curves, and electrochemical impedance spectroscopy (EIS). Morphological changes on the corroded nickel surface were completed by scanning electron microscopy (SEM).

2. Experimental methods

2.1. Electrodes and electrolysis cell

A classical three-electrode cell made of cylindrical borosilicate was used for electrochemical experiments. The counter-electrode was a large platinum grid. The reference electrode was a saturated mercurous sulphate electrode (SSE). The potential will be given with respect to this reference electrode without correction for ohmic drop. The working electrode was prepared of a cylindrical nickel rod of 0.2 cm² cross-sectional area from Good fellow (purity 99.999%). The lateral part of the nickel rod was coated by a cathaphoretic paint layer (PPG; W781-I1292+W975-G292), cured at 150 °C for 30 min to avoid the infiltration of corrosive solution in the lateral part of the electrode. Then, the nickel cylinder was embedded into an epoxy resin (Buhler, Epoxycure™).

Prior to measurements, working electrode was mechanically abraded with emery paper up to grade 4000 to yield a smooth and planar surface. Then, sample was thoroughly cleaned using acetone, rinsed with de-ionized water, and dried by argon or nitrogen flow.

Subsequently, the sample was transferred into the electrochemical cell. The electrode was set near the centre of cylindrical cell without rotation.

2.2 Corrosion test solutions

The electrolyte used was 0.5 M H_2SO_4 at room temperature prepared of analytical grade sulphuric acid and doubly distilled water in thermodynamic equilibrium to air; neither stirring nor bubbling of inert gas were made. The inhibitor used was L-cysteine ($\text{HSCH}_2\text{CHNH}_2\text{COOH}$) at two concentrations, 10^{-3} and 10^{-2} mole L^{-1} . The molar mass of this compound is 121.16. This substance will be called also as Cys.

2.3 Electrochemical devices and experimental procedures

Voltammetric measurements were performed using a potentiostat-galvanostat (METROHM®, AUTOLAB PGSTAT 20™) monitored by GPES software. The cyclic voltammetry were carried out with a scan rate of 10 mV s^{-1} . The potentiodynamic polarization curves were obtained with a scan rate of 0.5 mV s^{-1} with two independent measurements; one the potential scan towards more negative direction from 10 mV more positive from the open circuit potential (E_{corr}) up to $-1 \text{ V}_{\text{SSE}}$. Another one was the anodic potential scan from 10 mV more negative to the open circuit potential up to $-0.3 \text{ V}_{\text{SSE}}$.

Electrochemical Impedance Spectroscopy (EIS) measurements were realized using a potentiostat (SOTELEM® PG-STAT.Z1) at open circuit corrosion potential, E_{corr} , coupled with a frequency response analyser (SOLARTRON® SI 1255). For all EIS measurements, perturbing signal was the sine-wave signal of which amplitude was $10 \text{ mV}_{\text{rms}}$. The frequency range examined was from 10 kHz to 10 mHz. The impedance spectra were represented by an electrical equivalent circuit, and the values of these elements were determined by home-made software with a simplex algorithm.

2.4. SEM observations

For morphological observations, the samples were prepared and treated as describe above and immersed in the test solution during 24 h. The surface state was examined using scanning electronic microscope (LEICA® STEREOSCAN 440).

3. Results and discussion

3.1. Evolution of open circuit potential

The time evolution of the open circuit corrosion potential (E_{corr}) for nickel in 0.5 M H_2SO_4 in absence and in presence of different concentrations of cysteine (10^{-3} - 10^{-2} M) during one hour is illustrated in Figure 1.

Figure 1: Evolution the corrosion potential of a nickel electrode in aerated 0.5M H_2SO_4 without and with 10^{-3} or 10^{-2} M Cys.

In absence of Cys, E_{corr} shifts towards more positive direction. In its presence, the evolution of E_{corr} is different; first a marked increase of E_{corr} during the first 5 or 10 min after immersion followed by its decrease. The steady state potential is reached after about 30 minutes of immersion. At the steady state, E_{corr} showed a similar value in absence and in presence of Cys.

3.2. Cyclic voltammetry

Figure 2 shows the effect of Cys on the cyclic voltammograms (CV) of Ni, obtained in 0.5 M H_2SO_4 solution, without and with 10^{-3} or 10^{-2} M Cys. The potential scan started from $-1 \text{ V}_{\text{SSE}}$ up to $+0.12 \text{ V}_{\text{SSE}}$, then returned to $-1 \text{ V}_{\text{SSE}}$. The potential scan rate was 10 mV s^{-1} .

Figure 2: Cyclic voltammograms of Ni in 0.5 M H_2SO_4 without and with 10^{-3} or 10^{-2} M Cys

During anodic scan, the shape of the CV without Cys is consistent with that reported in other studies. According to the literature, the form of CV is related to the potential scan rate. At a high scanning rate the CV is characterized by a single anodic peak before passivity state. In contrast below 10 mV s^{-1} the appearance of two peaks was observed [27].

For the sharp peak located at lower anodic potential in absence of Cys, the peak potential E_{p1} is $-0.475 \text{ V}_{\text{SSE}}$ and the current density $I_{p1} = 7.01 \text{ mA cm}^{-2}$. In presence of Cys, this peak shift to more negative direction. At Cys concentration $[\text{Cys}]$ of 10^{-3} M , E_{p1} and I_{p1} are respectively $-0.533 \text{ V}_{\text{SSE}}$ and 3.07 mA cm^{-2} . At $[\text{Cys}] = 10^{-2} \text{ M}$, E_{p1} and I_{p1} changed to $-0.553 \text{ V}_{\text{SSE}}$ and 2.62 mA cm^{-2} . The addition of Cys in 0.5 M H_2SO_4 thus hinders the anodic dissolution of nickel and enhances the first passivation process leading to the peak 1.

Beyond the sharp current peak, the blunt peak leading to the passivation of nickel in a sulphuric acid was observed. The current density of this peak is located at $E_{p2} = -0.400 \text{ V}_{\text{SSE}}$ and $i_{p2} = 1.11 \text{ mA cm}^{-2}$. The addition of Cys does not change significantly this peak position whereas the current density decreases substantially. At 10^{-3} M , peak potential is located at $-0.396 \text{ V}_{\text{SSE}}$ for the peak current density of 0.254 mA cm^{-2} , and at 10^{-2} M , they are respectively $-0.398 \text{ V}_{\text{SSE}}$ and 0.141 mA cm^{-2} . The dissolution of nickel is hindered by the presence of Cys in the electrolyte. This is probably due to the adsorption of Cys on the nickel electrode surface preventing its active dissolution.

During the reverse scan, as it can be seen in Figure 3, the current density is much lower due to the presence of the passive film. The reduction of NiO reveals often by a cathodic peak at about $-0.5 \text{ V}_{\text{SSE}}$, but this phenomenon is not observed in this work.

Figure 3: Cyclic voltammograms in semi logarithmic plane of the nickel electrode in $0.5 \text{ M H}_2\text{SO}_4$ without and with 10^{-3} or 10^{-2} M Cys (The same results to those presented in Figure 2)

Figure 3 presents the results of Figure 2 in a semi-logarithmic scale, so that the current density during the back-scan can be evaluated readily. It can be noticed that in the passivity domain, the current density is smallest in absence of inhibitor, which may indicate that the presence of Cys somewhat destabilized the passive film. In other terms, the decrease of the peak current density is more closely linked to the hindering of the anodic dissolution rather

that the enhancement of the passive film formation. This aspect will be further discussed in §3.3.2.

3.3. Potentiodynamic polarization measurements

The typical anodic and cathodic polarization curves of nickel in 0.5 M H₂SO₄ in absence and in presence of 1 mM or 10 mM of Cys are shown in Figures 4 and 5. The potential scan rate was much slower than that used for cyclic voltammetry, i.e. 0.5 mV s⁻¹ instead of 10 mV s⁻¹.

3.3.1. Cathodic scan

It can be seen in Figure 4 that the cathodic reaction is controlled by the convective diffusion for $E_{\text{corr}} > E > -0.75 \text{ V}_{\text{SSE}}$. The plateau current density is ca. 17 $\mu\text{A cm}^{-2}$ in a good agreement with the reduction of dissolved oxygen controlled by diffusion for a stagnant solution. Its reaction can be expressed, similar to the case on Fe electrode [28]:

Therefore, the spontaneous corrosion current density will be mainly controlled by this process.

Figure 4: Cathodic polarization curves of nickel in 0.5M H₂SO₄ without and with 10⁻³ or 10⁻² M Cys; scan rate 0.5 mV s⁻¹

For potentials more negative than $-0.8 V_{SSE}$, the cathodic reaction increases linearly in $\log(I) - E$ plot. This reaction is allocated to the hydrogen evolution reaction by the reduction of hydronium ions according to Reaction (2):

The cysteine reduces clearly the hydrogen evolution reaction rate and has no effect on the reduction of dissolved oxygen, Reaction (1).

3.3.2. Anodic scan

The polarization curves collected during the anodic scan are presented in Figure 5. Compared with Figure 2, in absence of Cys, it can be noticed that the current density of the first peak is much smaller and the current density of the second peak is higher for this slow potential scan.

Anodic dissolution of nickel in sulphuric media has been studied extensively by de Gromobov and Shreir [29]. The first step of the Ni dissolution was attributed to the formation of the adsorbed reaction intermediate species $NiOH_{ad}$ [30-33]:

This intermediate species $NiOH_{ad}$ will precede two reactions. First, oxidation of the intermediate into Ni^{2+} i.e. the active dissolution leading to the corrosion of Ni:

On the other hand, oxidation and deprotonation of the same intermediate, leading to the passive species NiO :

Figure 5: Anodic polarization curves of nickel in 0.5M H₂SO₄ without and with 10⁻³ or 10⁻² M Cys; scan rate 0.5 mV s⁻¹

The Nernst equilibrium potential of Ni ↔ NiO is -0.53 V_{SSE}, corresponding to the first peak observed by cyclic voltammetry (Figure 2), since this peak is located at -0.559 V_{SSE} and the current density equal to 0.746 mA cm⁻². This current density is about one tenth' of that observed with the potential scan equal to 10 mV s⁻¹.

The second current peak is located at -0.320 V_{SSE} and the current density is 3.58 mA cm⁻². This current density is about three times as high as that observed with a fast potential scan. According to [29], the equilibrium potential of Ni ↔ Ni₃O₄ is -0.36 V_{SSE}. Consequently, the second current peak can be allocated to the formation of Ni₃O₄ though the following reaction:

The addition of Cys reduces the anodic current density near E_{corr}, and induces the disappearance of the first current peak. Besides, the second current peak observed by cyclic voltammetry is no longer observed clearly in the potential range used here, but I-E curve bends slightly towards a smaller current density. In other words, the current density of the first peak decreases whereas that of the second peak increases when the potential scan becomes slower. As a whole, in presence of Cys, the first peak disappears.

The cysteine is thus an anodic inhibitor for the dissolution process in Reaction (3) while it hinders the formation of Fe_3O_4 by Reaction (6). Such a phenomenon could be linked on one hand to the formation Ni-Cys adsorbate or that of insoluble a Ni-Cys complex that may thwart the formation of the passivity films.

3.3.3. Corrosion current density by voltammetry

Close to the corrosion potential E_{corr} , the first Stern-Geary relationship [34] may be applied, provided that the both anodic and cathodic processes, are purely additive, and that each processes follows an exponential law with respect to the potential. Then, the overall current density is given according to the following relation:

$$I = I_{\text{corr}} \cdot \{ \exp[b_a(E - E_{\text{corr}})] - \exp[b_c(E - E_{\text{corr}})] \} \quad (7)$$

Where I_{corr} is corrosion current density (A cm^{-2}), b_a and b_c are respectively the anodic and cathodic Tafel constants (V^{-1}).

It will be worth to mention that sometimes, the Tafel constant is allocated to the slope of polarization curves in $\log(I) - E$ scale, i.e. Tafel slope in unit of V dec^{-1} . Let this constant be represented by β , the two constants b and β are linked through the following expression:

$$b = \frac{\ln(10)}{\beta} \quad (8)$$

I_{corr} , E_{corr} , b_a and b_c , were evaluated from the experimental results by using a user defined function of “Non-linear least squares curve fit” implemented in the graphic software used (Origin™, OriginLab®). Since the anodic polarization may modify the adsorption of Cys by the dissolution of substrate nickel during an initial polarization of cathodic scan, the anodic scan was used to apply Equation (7). 40 points, i.e. 40 mV from the starting potential used for this calculation.

Figure 6a shows the polarization curve obtained in absence of and in presence of Cys. In can be remarked that the polarization curve show a smaller slope when the concentration of Cys increases. Figure 6b displays the same data but in a semi-logarithmic scale, so called Tafel plot. The non linear parameter fittings were carried out with the absolute value of the logarithm of current density, $\log(|I|)$. The results of fitting (in curve) are overlaid on the

experimental data (in symbols). It can be seen in Figure 6, a good agreement between the calculated and the fitted polarization data as well for Figure 6a as Figure 6b.

Besides, in Figure 6b, one may notice that the extrapolation of the cathodic branches for various Cys concentration tend to overlap. This remark confirms that the cathodic current density near E_{corr} , is determined mainly by the limiting diffusion current density of the dissolved oxygen as stated on Figure 4.

Figure 6: Comparison between experimental and calculated I-E curves.

The corrosion rate is thus essentially determined from the anodic polarization curves. The inhibitory efficiency in percent IE(%) was evaluated from the following relationship:

$$IE(\%) = 100 \cdot \frac{I_{corr}^0 - I_{corr}}{I_{corr}^0} \quad (9)$$

Where I_{corr}^0 and I_{corr} denote the corrosion current densities, in absence and in presence of Cys, respectively. Table 1 summarizes the results of non-linear regression calculation with I-E curve and log(I)-E curves. They are denoted by suffix "lin" or "log" respectively.

Table 1: Corrosion parameters determined by non linear regression calculation according to Equation 7 for experimental results

[Cys] mol L ⁻¹	E _{corr} V _{sse}	I _{corr} lin μA cm ⁻²	IE _{lin} (%)	I _{corr} log μA cm ⁻²	IE _{log} (%)
0	-0.6623	5.22±0.01	-	5.22±0.39	
10 ⁻³	-0.6549	3.70±0.25	29.1±2.0	5.78±0.31	-10.7±1.3
10 ⁻²	-0.6370	4.95±0.39	6.03±.04	4.27±0.24	18.1±2.4

The values of inhibitory efficiency IE(%) are also included in Table 1. These values show that Cys for the two concentrations tested inhibits only slightly the corrosion of nickel in acid solutions. This statement corroborates the fact that the cathodic process is determined in major part by the cathodic reaction of dissolved oxygen near E_{corr} controlled by the convective diffusion.

The polarization resistance R_p was also determined from the slope of the current-potential curve at the corrosion potential:

$$R_p = \left. \frac{dE}{dI} \right|_{E_{corr}} \quad (10)$$

From Equation (7), one gets readily so called the second Stern-Geary equation [31]:

$$I_{corr} = \frac{1}{R_p \cdot (b_a - b_c)} = \frac{B}{R_p} \quad (11)$$

According to the obtained results, polarization resistance gets a higher value with increasing concentration of the cysteine, as can be seen in Figure 6a. If the value of R_p is considered to determine the corrosion rate with a constant the Stern-Geary coefficient, B , one may have erroneous conclusion on the inhibitory effect of cysteine on the corrosion of nickel in 0.5 M H_2SO_4 . That is to say, b_a and b_c are dependent on cysteine concentration.

Figure 7 presents the absolute value of b_a and b_c determined from linear I-E relationship and those from the Tafel plot ($\log(|I|)$ -E) for different Cys concentrations. As this is the case for the corrosion current density, with the same data set, the values of parameter obtained by regression calculations are different. However, the comparison of experimental data

(symbols) and fitted data (lines) showed an excellent quality of the fitting procedures. R^2 is for the whole cases, greater than 0.9998. The difference observed is probably due to the data treatments, I or $\log(|I|)$.

Figure 7: Tafel constants b_a and b_c are determined from Figures 6a (I) and 6b ($\log(|I|)$)

b_c varies is little, though scattered, and values about $9 V^{-1}$. This small value corresponds well to the system mainly controlled by the limiting diffusion current density. In contrast, b_a decreases with increasing [Cys] roughly by an exponential-type decay curve. The presence of cysteine therefore modifies the activation energy of the anodic process, thus the nature of

anodic reaction itself. The Stern-Geary coefficient B decreases thus with increasing $[Cys]$ which explains the apparent contradiction with R_p value and the corrosion current density.

3.4. Electrochemical impedance spectroscopy

To obtain additional information on the electrochemical processes taking place at the interface in absence and in presence of Cys, electrochemical impedance measurements were carried out. The electrode was left alone for one hour and then the impedance measurements were started at the open circuit potential E_{corr} from high to low frequencies.

Figure 8a shows, the impedance spectra in Nyquist plot of Nickel electrode immersed in an aerated 0.5M H_2SO_4 in absence and in presence of Cys (10^{-3} or 10^{-2} M). One capacitive loop was observed for three cases with a small tail at the low frequency end, $f < 0.1$ Hz. This

impedance behaviour will be explained by the fact that, in spite of one hour stabilization period, the system was not entirely reached at its steady state.

Figure 8: Electrochemical impedance diagrams representing Nyquist (a) and Bode (b) plots of Nickel in 0.5M H₂SO₄ without and with 10⁻³ or 10⁻² M of Cys

In the Bode diagrams, Figure 8b, only one maximum of phase-shift ϕ at intermediate frequencies is observed in agreement with Nyquist plot exhibiting one capacitive loop.

The maximum phase angle is less than 80° in agreement with a depressed feature observed in Nyquist plot, Figure 8a. However, the spectra observed in the Nyquist diagram or the phase shifts in the Bode diagram are not well symmetrical. This behaviour suggests the presence of two time constants badly separated. Indeed, a non-linear regression calculation with one time constant revealed a marked systematic error. That is, in the Nyquist plot, around its apex, all calculated points are located above the experimental points, and for low and high frequency extremities, all calculated data are located below the experimental data. Therefore, the presence of two depressed capacitive loops is taken into account. The equivalent electrical circuit with two CPE//R ladder connexion is used as illustrated in Figure 9.

Figure 9: Equivalent electrical circuits used to represent impedance data of Nickel.

The origin of these, circuit-elements are allocated to:

R_s : Solution resistance ($\Omega \text{ cm}^2$),

Q_d : CPE element associated with the double layer capacitance ($\text{F cm}^{-2} \text{ s}^{n_d-1}$),

R_t : Charge transfer resistance ($\Omega \text{ cm}^2$),

C_F : Faradaic capacitance due to the surface relaxation of NiOH_{ad} or NiO ($\text{F cm}^{-2} \text{ s}^{n_F-1}$),

R_F : Faradaic resistance associated with reactions 3 to 5 ($\Omega \text{ cm}^2$),

n_d, n_F : CPE coefficient (dimensionless).

High frequency loop is generally associated with the relaxation of the double layers capacitance in parallel with the charge- transfer resistance [35, 36]. Home-made non-linear regression calculation based on Simplex algorithm was used to evaluate the value of each element defined in Figure 9.

Effective capacitances for the double layer C_d and the faradaic capacitance C_F were calculated instead of CPE (Q and n) according to the equation proposed by Brug et al. [37].

$$C_{eff} = Q^{\frac{1}{n}} \cdot \left(\frac{1}{R_1} + \frac{1}{R_2} \right)^{\frac{n-1}{n}} \quad (12)$$

The results of regression calculation are presented in Figure 10. No systematic error was observed during the calculation and χ value is, for three cases examined less than 0.6 %. The

χ value represents the mean error of real and imaginary part with respect to the impedance modulus, indicating the validity of the equivalent circuit model used here.

Figure 10: Variation of the polarization resistance (R_p), the electrolyte resistance (R_s), the double layer capacitance (C_d) and the faradaic capacitance (C_f) for Nickel in 0.5M H_2SO_4 with and without of Cys

It can be seen in Figure 10 that the calculated electrolyte resistance R_s is independent of experiments, and the average value is close to $3 \Omega \text{ cm}^2$. The value of C_d decreases slightly in presence of Cys; $47 \mu\text{F cm}^{-2}$ in absence and $32 \mu\text{F cm}^{-2}$ in presence of 10mM Cys. These values are in good agreement with the double layer capacitance. The adsorption of Cys at nickel surface leads to only a slight decrease of the double layer capacitance. The cysteine being small and polar molecule, this is why the adsorption of this species at the nickel surface induces only a small decrease of the double layer capacitance. The value of C_f , which is directly related to the electrical charge stored on nickel surface. The peak potential is not very far from E_{corr} as can be seen in Figure 5, thus it is very likely that this capacitive behaviour is due to the relaxation of the reaction intermediate of active dissolution NiOH_{ad} (Reaction 3) or that of passive species NiO (Reaction 5).

C_f decreases steeply in presence of 1 mM Cys then decreases slightly. In absence of this compound, C_f is equal to $330 \mu\text{F cm}^{-2}$, this capacitance becomes close to $70 \mu\text{F cm}^{-2}$ at 1 mM Cys and $45 \mu\text{F cm}^{-2}$ at 10 mM Cys. Therefore the presence of this molecule lessens the reversible species at the electrode surface. This will be the reason that the passive film in presence of cysteine is less protective than its absence as stated in §3.2. and §3.3.2.

The variation of the polarization resistance R_p ($=R_t+R_f$), which corresponds to the chord of Nyquist plot, increase in presence of Cys. This increase is, however, moderate at 10 mM Cys compared for instance for the case of the corrosion of Cu-Ni alloys by this molecule [26]. This result confirms a protective effect provided by cysteine against corrosion of nickel in an acid medium is weak since the corrosion rate is in major part controlled by the diffusion limiting current density of dissolved oxygen.

3.5. Surface state after the corrosion test

Inhibitive efficiency of cysteine evaluated by electrochemical methods is rather poor for nickel electrode in sulphuric acid solution whereas this molecule is efficient for copper-nickel alloy [26] and copper [24,36,38,39]. To verify if the effect of Cys, the surface state of the nickel electrode was observed by SEM after 24 hours immersion in 0.5 M H_2SO_4 in absence of in presence of Cys

Figure 11: SEM images of the nickel surface after 24 h immersion in 0.5M H_2SO_4 ;
(a) Without inhibitor, (b) with 1mM Cys and (c) with 10 mM Cys

Figure 11 presents the SEM pictures. It can be noticed that the electrode surface after the corrosion test is only slightly improved in presence of Cys corroborating the results obtained by electrochemical methods.

3.6. Adsorption mechanism of cysteine

As reported in the literature [40-42], inhibition efficiency depends on the number of adsorption sites in the molecule and their charge density, molecular size, and the mode of interaction with the metal surface. According to our results, the inhibition of nickel corrosion in sulphuric acid medium by Cys is moderate. At 1 or 10mM, the corrosion efficiency is evaluated less than 30%. If the adsorption of cysteine would decrease the reduction reaction of dissolved oxygen, and coupled with the decrease of anodic dissolution, one may expect a higher protective effectiveness. However, this is not the case; one may wonder why the results obtained in this study with Cys are so deficient compared to those reported for other systems, namely carbon steel or copper alloys. Other amino acids and organic compounds may give also a higher corrosion protection.

One of the reasons is probably due to the fact that, as it was reported [43] the nickel surface is positively charged in H_2SO_4 solution. Also in acid medium, the neutral Cys, will be protonated at the amino function ($\text{HSCH}_2\text{CH}(\text{CO}_2\text{H})\text{NH}_3^+$). Thus, it is difficult for the positively charged inhibitor molecules to approach the positively charged metal surface because of the electrostatic repulsion. Under these situations, the SO_4^{2-} ions should first be adsorbed onto the anodic area, i.e. positively charged metal surface, creating negatively charged sites. After this preliminary step, the cysteine will be adsorbed by electrostatic interactions with negatively charged nickel surface at anodic sites. Thus, the positively charged inhibitor molecules form a protective film with Ni-Cys complex as illustrated in Figure 12.

Figure 12: Schematic representation of Cys absorption.

This process will induce a decrease of anodic current density as observed experimentally. With Figure 5 at $-0.61 V_{SSE}$ where the effect of cathodic current density becomes negligible in anodic polarization curve, it can be noticed that the current density is divided by 10 at 1 mM Cys, and by 20 at 10 mM Cys. The cysteine is thus a good anodic inhibitor. In contrast, the Ni-Cys complex film has little effect on the cathodic reduction rate of dissolved oxygen, and this process governs essentially the overall poor inhibitive efficiency.

4. Conclusion

The effect of cysteine molecule on the corrosion of nickel in 0.5 M H_2SO_4 solution was studied using electrochemical and SEM observation of corroded surface. Both voltammetric studies and impedance spectroscopy showed relatively poor inhibitory properties of this molecule. Cysteine decreases significantly the anodic current density, thus this molecule is an anodic-type inhibitor. The anodic Tafel slope decreases markedly by addition of cysteine, and suppress the first anodic current peak. The addition of cysteine in sulphuric acid modifies therefore the anodic process of nickel electrode. The impedance spectrum with faradaic capacitive behaviour is explained by the relaxation of anodic species, anodic reaction intermediate $NiOH_{ad}$ or the passive species leading to the first current peak NiO . The decrease of the double layer capacitance in presence of cysteine in H_2SO_4 indicates its adsorption or the formation of Ni-Cys complex on the metal surface. SEM images confirm a poor inhibitory effect of cysteine.
