ABSTRACT

Mitochondrial metabolism is a tightly regulated process that plays a central role throughout the lifespan of hematopoietic cells. Herein, we analyze the consequences of the mitochondrial oxidative phosphorylation (OXPHOS)/metabolism disorder associated with the cell-specific hematopoietic ablation of apoptosis-inducing factor (AIF). AIF-null ($AIF^{-/Y}$) mice developed pancytopenia that was associated with hypocellular bone marrow (BM) and thymus atrophy. While myeloid cells were relatively spared, the B-cell and erythroid lineages were altered with increased frequencies of precursor B-cells, pro-erythroblasts I, and basophilic erythroblasts II. T-cell populations were dramatically reduced with a thymopoiesis blockade at a double negative (DN) immature state, with DN1 accumulation and delayed DN2/DN3 and DN3/DN4 transitions. In BM cells, the OXPHOS/metabolism dysfunction provoked by the loss of AIF was counterbalanced by the augmentation of the mitochondrial biogenesis and a shift towards anaerobic glycolysis. Nevertheless, in a caspase-independent process, the resulting excess of reactive oxygen species compromised the viability of the hematopoietic stem cells (HSC) and progenitors. This led to the progressive exhaustion of the HSC pool, a reduced capacity of the BM progenitors to differentiate into colonies in methylcellulose assays, and the absence of cell-autonomous HSC repopulating potential *in vivo*. In contrast to BM cells, $AIF^{-/Y}$ thymocytes compensated for the OXPHOS breakdown by enhancing fatty acid β -oxidation (FAO). By over-expressing CPT1, ACADL and PDK4, three key enzymes facilitating FAO (e.g., palmitic acid assimilation), the $AIF^{-/Y}$ thymocytes retrieved the ATP levels of the $AIF^{+/Y}$ cells. As a consequence, it was possible to significantly re-establish $AIF^{-/Y}$ thymopoiesis *in vivo* by feeding the animals with a high-fat diet complemented with an antioxidant. Overall, our data reveal that the mitochondrial signals regulated by AIF are critical to hematopoietic decision-making. Emerging as a link between mitochondrial metabolism and hematopoietic cell fate, AIF-mediated OXPHOS regulation represents a target for the development of new immunomodulatory therapeutics.

Key Words: AIF, Hematopoiesis, Metabolism, Mitochondria, ROS

INTRODUCTION

Mitochondria are wide-ranging functional organelles that play a vital role during hematopoiesis by providing energy in the form of ATP and by generating reactive oxygen species (ROS) that regulate proliferation, differentiation, activation, and self-renewal.¹⁻⁴ For example, a fine regulation of mitochondrial ROS production is needed to maintain the equilibrium between quiescent and cycling BM hematopoietic stem cells (HSC).^{2, 5-7} In contrast, high levels of mitochondrial ROS are detrimental to HSC and can lead to their elimination by programmed cell death (PCD).⁷ The relevance of mitochondrial oxidative phosphorylation (OXPHOS) in determining HSC fate is also signified by the metabolic changes that occur during the transition from a quiescent to a cycling/activated state.⁸ Concerning thymopoiesis, less is known about the OXPHOS implication in the differentiation of double negative (DN) progenitor cells. However, a fine-tuning between ROS and glycolytic activation appears important for DN1-to-DN4 transitions.^{9,10}

AIF, a Janus mitochondrial protein that is encoded by the *Aifm1* (*Aif*, *Pdcd8*) gene on the X-chromosome, has been implicated in maintaining mitochondrial electron transport chain (ETC) function.¹¹⁻¹⁴ After its translocation to the nucleus following an apoptotic insult, AIF also participates in the modulation of caspase-independent PCD.¹⁵⁻²¹ Under pathological conditions, the mitochondrial function of AIF is critical to inhibiting tumor metastasis by modulating PTEN phosphatase activity.²² Moreover, human mutations in AIF result in acute pediatric mitochondrialopathies (encephalopathy, infantile motor neuron disease, and early prenatal ventriculomegaly).²³⁻²⁵ Concerning the immune system, studies in the Harlequin (Hq) mouse strain (which has a ~70% non-tissue specific reduction in AIF expression) indicate that, in peripheral mature T-cells, low AIF expression leads to enhanced susceptibility of T-cell blasts to activation-induced cell death and reduced sensitivity to neglect-induced cell death. In this model, the HSC, B-cells and other hematopoietic lineages do not exhibit apparent abnormalities.^{26, 27} Contrary to these results, a work in which *Aif* was ablated around the DN3 stage of thymocyte development reported that AIF-loss had no impact on T-cell development. In the same study, the use of the CD19-cre strain indicated that AIF was not required for B-cell development and function.²⁸

Herein, by generating an original mouse model in which *Aif* was ablated early during hematopoiesis, we have broadly investigated the role of this protein and the AIF-regulated mitochondrial OXPHOS metabolism in the development and fate of immune cells. Our new mouse strain demonstrates that early AIF deficiency provokes, in neonate and adult mice,

pleiotropic consequences on normal hematopoiesis, including LT-HSC, ST-HSC and MPP loss, the arrest of thymopoiesis, and a delayed development of B-cell and erythroid lineages. Importantly enough, our mouse model also illustrates metabolic adaptive responses associated to OXPHOS dysfunction: BM cells shift towards anaerobic glycolysis, whereas thymocytes favor fatty acid β -oxidation (FAO).

RESULTS

AIF ablation in hematopoietic cells resulted in pancytopenia and aberrant thymocyte, B-cell, and erythroid development

To investigate the influence of AIF in hematopoiesis, we crossed a newly generated *Aifm1* floxed mouse with a *Vav1-cre* strain that drives early Cre recombinase expression specifically in hematopoietic cells, including HSC.²⁹ Excision of *Aifm1* exon 11 on the X-chromosome generated a stop codon, which resulted in a male progeny null for AIF (*AIF*^{-Y} mice) (Supplementary Figure 1).

At 7 days of age, *AIF*^{-Y} and *AIF*^{+Y} littermates (WT mice) presented a similar phenotype with a normal BM cellularity. However, in contrast to *AIF*^{+Y}, the thymus of KO animals was markedly smaller (Figure 1a). The *AIF*^{-Y} newborns developed normally until they were 21 days old, and after that they presented a loss of BM cellularity, a tiny thymus, and signs of severe anemia (Figure 1a, 28-day-old mice pictures), which was followed by mice death (Figure 1b). White cells, red cells, and platelet counts from the peripheral blood confirmed that *AIF*^{-Y} mice displayed progressive pancytopenia (Figure 1c). Between 21 and 28 days after birth, *AIF*^{-Y} animals exhibited severe hypocellularity of the BM and spleen. Moreover, the number of thymocytes in these animals, which is close to zero at birth, did not increase with age. Finally, the lymph node cellularity was very low in the KO mice, with no observed evolution and even a complete collapse in the 28-day-old animals (Figure 1d).

To better analyze the hematopoietic lineages in *AIF*^{+Y} and *AIF*^{-Y} mice, we performed cell-specific immunophenotyping. In the BM, although no significant differences were recorded in 7-day-old animals, erythroid (Ter119⁺), macrophagic/monocytic (CD11b⁺Gr1⁻), B-lymphoid (B220⁺), and T-lymphoid (CD3⁺) cells were severely decreased in 21- and 28-day-old *AIF*^{-Y} animals (Figure 1e). In the thymus of the KO mice, T-cell development was blocked at the CD4⁻CD8⁻ double negative (DN) stage. For example, at 21 days of age, WT mice exhibited more than 85% CD4⁺CD8⁺ DP thymocytes, while KO animals had ~87% DN thymocytes (Figure 1f and Supplementary Figure 2). Our analysis of other hematopoietic lineages revealed that, in contrast to what had been previously reported in the Hq mouse strain^{26, 27} or in the CD19-Cre mouse model,²⁸ the B-cell and erythroid lineages were also affected by the early AIF deficiency. This was manifested by increased frequencies of precursor B-cells (IgM⁺IgD⁺) in the BM and spleen (Figure 1g and Supplementary Table 1), as well as increased frequencies of pro-erythroblasts I (CD71⁺Ter119^{int}) and basophilic erythroblasts II (CD71⁺Ter119⁺) in the spleen (Figure 1h).

By crossing *Aifm1*-floxed mice with a tamoxifen-inducible Rosa26-CreERT2 mouse strain,³⁰ we confirmed that the loss of AIF in 3-month-old adult mice also provoked major hematopoietic alterations. These included a reduction in BM and thymus cellularity, which resulted in death of the mice between 25 and 65 days after the first tamoxifen injection, and a significant delay in T-cell development (Supplementary Figures 3a-c). Overall, these findings indicate that AIF ablation resulted in pleiotropic consequences that affected hematopoiesis in neonatal and adult mice.

AIF loss provoked mitochondrial OXPHOS dysfunction and BM metabolic recalibration

As indicated above, AIF has been largely implicated in maintaining ETC stability and function.¹²⁻¹⁴ Thus, we tested whether the severe phenotype observed in *AIF*^{-/-} mice was directly related to OXPHOS dysfunction in BM cells. ETC integrity was verified using an immunoblot approach which indicated that, after the loss of AIF, whole BM cells experienced a significant reduction in the mitochondrial complex I subunit NDUFA9 and a moderate reduction in the complex III UQCRC2 and complex IV COX4I2 subunits. By contrast, complex II SDHA and complex V ATP5B proteins were not affected by the loss of AIF (Figure 2a and Supplementary Figure 4a). These observations are in accordance with the “solid-state” model of ETC structure that organizes the mitochondrial complexes I, III, and IV in a unique “supercomplex” entity in which the alteration in one complex directly affects the two others.³¹⁻³³ Note that the structural mitochondrial protein VDAC1 appears over-expressed in the BM KO cells, suggesting an augmentation of the mitochondrial mass. Morphologically, compared to WT cells, mitochondria from *AIF*^{-/-} cells lacked a normal tubular structure and exhibited swollen irregular tubules associated with changes in the internal membrane organization (Figure 2b).

The monitoring of oxygen consumption rate (OCR) by Seahorse and Clark electrode revealed that *AIF*^{-/-} cells exhibited a significant reduction in both basal oxygen consumption and total oxidative capacity (Figure 2c and Supplementary Figure 4b). In spite of that, the complex I inhibitor amytal abolished the remaining oxygen consumption of *AIF*^{-/-} cells, indicating that complex I remains somewhat functional in the KO cells. Moreover, as indicated by the addition of the complex V inhibitor oligomycin, electron transport was still coupled to ATP synthesis (Figure 2c and Supplementary Figure 4b). Finally, the detailed analysis of the individual complex activities, measured by monitoring OCR in permeabilized cells, revealed that ETC activities of *AIF*^{-/-} cells were ~ 40 % lower than those measured in WT cells (Supplementary Figure 4c). Together, the ETC and OXPHOS alterations associated to AIF deficiency in BM cells provoked a diminution in the mitochondrial transmembrane potential ($\Delta\Psi_m$) and an

enhancement in the generation of mitochondrial ROS (Figures 2d and e and Supplementary Figures 3d and e).

At the cellular level, the results obtained with the specific marker Mitotracker Green and the genetic signature of PGC1 α expression confirm that the mitochondrial defects associated with AIF loss were counterbalanced in BM cells by the augmentation of mitochondrial mass (Figure 2f). This was accompanied by a shift to anaerobic glycolysis, as revealed by the increase in: (i) glucose uptake, measured by 2-NBDG assimilation (Figure 2g); (ii) extracellular acidification rate (ECAR), a marker of anaerobic glycolysis that indicated lactic acid production, assessed in the presence of glucose and blocked by the glycolytic inhibitor 2-Deoxy-glucose (2-DG) (Figure 2h); and (iii) lactate release (Figure 2i). The inhibition of caspases does not modify this glycolytic picture (Supplementary Figure 5), indicating that the metabolic change is not due to the initiation of an apoptotic process. Anyhow, the metabolic reprogramming was further validated by a broad metabolomic approach, which corroborated that the components of the glycolytic pathway (e.g., glucose and fructose) and the general carbohydrate metabolism were enhanced in *AIF*^{-/-} BM cells. The metabolomic approach also revealed that AIF-null BM cells had reinforced amino acid metabolic pathways (Figure 2j and Supplementary Table 2). The Seahorse OCR monitoring of the major amino-acid substrate, glutamine, which enters the mitochondria as α -ketoglutarate and is converted to CO₂ and H₂O in an oxygen-consuming process, indicated that the BM cells do not use this pathway as a source of energy (Supplementary Figure 6a). The amino-acid increase seems to reflect here the low ability of AIF KO BM cells to proliferate, which could result in a general amino-acidic accumulation. Thus, the glycolytic shift seems sufficient to maintain the ATP levels of the *AIF*^{-/-} BM cells close to those measured in WT cells in both neonatal and adult mice (Figure 2k and Supplementary Figures 3f and 6b). Overall, our data reveal that the loss of AIF in BM cells results in a defective OXPHOS that is counterbalanced by the stimulation of mitochondrial biogenesis and a broad metabolic shift that reinforces anaerobic glycolysis.

Mitochondrial OXPHOS and metabolism defects associated with the absence of AIF modify the repopulating potential of BM hematopoietic progenitors

AIF^{-/-} animals displayed progressive pancytopenia that affected all hematopoietic subsets. This finding suggested that AIF was required to control HSC homeostasis. To confirm the role of AIF in hematopoietic progenitors, we first investigated the HSC-enriched Lin⁻Sca-1⁺Kit⁺ (LSK) fraction in both E17.5 embryos and 7- to 28-day-old animals. Compared to WT mice, the percentage and absolute cell number of AIF-deficient LSK cells markedly declined between 7

and 14 days after birth (Figure 3a). Additionally, analysis of HSC (LT-HSC, ST-HSC), multipotent progenitors (MPP), common lymphoid progenitors (CLP), myeloid progenitors (CMP and GMP) and megakaryocyte/erythrocyte progenitors (MEP) showed that the loss of cells affected all HSC and progenitor subsets. Low cellularity could already be observed in 7-day-old $AIF^{-/Y}$ mice, and the difference with the WT animals increased at 14 days after birth. At the end, the hematopoietic subsets were nearly undetectable in the 28-day-old animals (Figure 3b). The LT-HSC, ST-HSC, and MPP subpopulations were also significantly affected in adult tamoxifen-treated $AIF^{-/Y}$ mice (Supplementary Figure 3g).

We next assessed the functional properties of BM progenitors using *ex vivo* colony-forming assays. Compared to WT cells, the fetal liver (FL) KO cells obtained at E15.5 or BM cells from $AIF^{-/Y}$ animals at 7 or 21 days of age had very low clonogenic capacity (Figure 3c). It is important to take into consideration the time of methylcellulose culture (10 days), which shifted the 7-day-old time point to a 17-day-old equivalent and the 21-day-old cells to a 31-day-old equivalent. Thus, as could be expected, the BM cells from 21-day-old animals presented a nearly non-existent clonogenic capacity. Moreover, the colonies formed by all KO cells, which were significantly smaller than those generated by WT cells, were mainly derived from cells with an erythroid (CFU-E/BFU-E), granulocyte (CFU-G), or monocytic (CFU-M) phenotype. Note that the $AIF^{-/Y}$ cells presented a lower clonogenic potential, even if we recorded a similar percentage of LSK in WT and KO E17.5 and 7-day-old mice (Figure 3a). Lastly, we demonstrated that the retroviral reintroduction of mAIF in KO cells significantly restored the clonogenic potential of $AIF^{-/Y}$ cells (Figure 3d). Overall, our colony-forming approaches confirm that the proliferation and differentiation defects of these KO cells result from the AIF absence.

We then performed both non-competitive and competitive transplantation assays to test the hematopoietic progenitor-repopulating capacities *in vivo* using CD45.2 donor cells that we injected into lethally irradiated CD45.1 recipient mice. In non-competitive assays, approximately 50% of recipient mice grafted with $AIF^{-/Y}$ BM cells died. The surviving mice had very few CD45.2 donor cells in the blood or BM, as revealed by quantification at 2, 6, and 8 weeks post-transplantation (Figure 3e). Similarly, in competitive transplantation experiments, AIF-deficient LSK cells yielded lower levels of reconstitution compared with WT LSK cells (Figure 3f). Finally, we tested *in vivo* the repopulating capacities of the $AIF^{-/Y}$ cells transduced with mAIF. As depicted in the Figure 3g, the reintroduction of mAIF into $AIF^{-/Y}$ FL cells significantly rescued their repopulating potential *in vivo*, confirming the cell-autonomous AIF requirement in HSC and progenitor cells.

High levels of ROS induced *AIF*^{-/-} HSC and progenitors exhaustion

We next investigated the mechanisms that underlie AIF-mediated HSC and progenitors exhaustion. We first observed that, as previously described for the bulk BM, anaerobic glycolysis is enhanced in these AIF KO subsets (Figures 4a). Moreover, compared with WT cells, mitochondrial ROS levels were significantly augmented (Figures 4b). Finally, *AIF*^{-/-} HSC and progenitors presented increased frequencies of DNA damage (revealed by positive γ H2AX staining) and cell death (measured by a double Annexin-V/7AAD labeling) (Figures 4c-d).

Using the antioxidant N-acetyl-cysteine (NAC), we set up to verify whether the high levels of ROS generated by the AIF loss-associated OXPHOS dysfunction (Figure 2) compromised the viability of HSC and progenitor cells. We first confirmed that treatment of *AIF*^{-/-} BM cells with NAC suppressed the excess of mitochondrial ROS (Figure 4e). Further, using a colony-forming assay with BM cells, we observed that the addition of NAC to methylcellulose medium significantly favored the development of *AIF*^{-/-} BM cells into colonies (Figure 4f). Notably, in the presence of NAC, *AIF*^{-/-} BM cells also developed into a large number of immature GEMM colonies, which would have never formed in the absence of antioxidant. Finally, the addition of NAC in the drinking water administered to the dams allowed for the *in vivo* rescue of LT-HSC, ST-HSC, and MPP in the *AIF*^{-/-} newborn mice (Figure 4g).

Mitochondrial OXPHOS regulated thymocyte differentiation and fate

To analyze the developmental defaults of the *AIF*^{-/-} thymocytes (Figure 1f), we first performed detailed immunophenotyping. In E15.5 thymic lobes, only DN precursor thymocytes were observed and an analysis of DN1-to-DN4 subpopulations did not reveal significant differences between the WT and KO animals (Figure 5a and Supplementary Table 3a). At E17.5, loss of AIF restricted both the DN3-to-DN4 transition and the generation of DP cells. Furthermore, thymus analysis in 7, 21, and 28-day-old mice indicated that thymocytes from the *AIF*^{-/-} progeny: (i) remained at a DN immature state; (ii) accumulated at the DN1 stage of differentiation; and (iii) exhibited delayed DN2/DN3 and DN3/DN4 transitions. Additionally, cellular counts revealed a significant reduction in the DN2, DN3, and DN4 subsets in *AIF*^{-/-} mice (Supplementary Figure 7). By using cKit/CD24 co-labeling, we further analyzed the phenotype of the DN1 *AIF*^{-/-} prothymocytes. Compared to WT, the DN1 compartment of the AIF-null 7-day-old mice showed a relative high number of DN1b cells, low levels of DN1c prothymocytes, and the accumulation of the less proliferative DN1e subset. In 21-day-old mice, as expected by the diminution of the CLP precursors in the BM (Figure 3b), we detected an exhaustion of the canonical T progenitors DN1a/DN1b. This was accompanied by the increase in the percentage of DN1e cells (75% of the

total DN1 cells; Figure 5b and Supplementary Table 3b). Of note, the differences observed between the WT and *AIF^{-Y}* thymocytes did not appear to be caused by impaired TCR β recombination (Figure 5c). Overall, our findings indicated that, similarly to what we had observed in BM cells, the loss of AIF influenced thymocyte differentiation and fate.

As for BM cells, we next tested whether the *AIF^{-Y}* undifferentiated thymocyte phenotype was directly related to the mitochondrial OXPHOS alteration. Morphologically, compared to WT thymocytes, *AIF^{-Y}* mitochondria exhibited a severe internal membrane disorganization that was associated to the loss of normal tubular structure (Figure 6a). OCR monitoring revealed that *AIF^{-Y}* thymocytes exhibited a ~50% reduction in both basal oxygen consumption and total oxidative capacity (Figure 6b). Thus, compared to *AIF^{-Y}* BM cells, the *AIF^{-Y}* thymocytes showed a more severe OXPHOS dysfunction that provoked a reduction in $\Delta\Psi_m$ and the high generation of mitochondrial ROS (Figures 6c and d and Supplementary Figures 3h and i). Surprisingly, contrary to what is typically observed in the BM cells, these mitochondrial alterations were not counterbalanced either by an increase in the mitochondrial mass or by a shift towards anaerobic glycolysis (Figures 6e and f). Consequently, the cellular ATP levels of the *AIF^{-Y}* thymocytes dropped significantly (Figure 6g and Supplementary Figure 3j).

Searching for a metabolic adaptive alternative in *AIF^{-Y}* thymocytes, we performed a qRT-PCR approach that revealed the significant up-regulation of three key fatty acid β -oxidation (FAO) facilitating enzymes: CPT1, ACADL, and PDK4 (Figure 7a). The overexpression of FAO facilitating enzymes in *AIF^{-Y}* thymocytes was corroborated by RNAscope, a specific fluorescence in situ hybridization technique that allows for the visualization of mRNAs in single cells³⁴ (Figure 7b). Note that the metabolic reprogramming induced by AIF loss in thymocytes, including the mitochondrial alterations, the low glycolytic rate, and the overexpression of FAO facilitating enzymes, was not only confirmed when comparing the *AIF^{+Y}* and *AIF^{-Y}* DN thymocyte fractions, but also persisted even if the *AIF^{+Y}* DN compartment presented a more important OXPHOS activity than those measured in the whole *AIF^{+Y}* thymocyte population (Supplementary Figure 8). Next, we biochemically confirmed, by an OCR Seahorse assay, the capacity of KO thymocytes to perform FAO. Compared to WT, we observed the increased respiratory capacity of the *AIF^{-Y}* thymocytes in the presence of palmitate (Figure 7c, left panel). In these conditions, the respiratory capacity of the *AIF^{-Y}* thymocytes was downregulated by the irreversible CPT1 inhibitor Etomoxir, corroborating the key participation of this enzyme in the palmitate assimilation of these cells (Figure 7c, right panel). Altogether, our data indicate that the OXPHOS dysfunction associated to AIF loss could be counterbalanced in thymocytes by

FAO stimulation. As for BM cells, the inhibition of caspases does not modify this metabolic reprogramming (Supplementary Figure 9).

The ablation of AIF differentiated the metabolic flexibility of thymocytes and BM cells

Finally, following our above results concerning the functional FAO detected in *AIF*^{-/-} thymocytes and considering that a ketogenic diet has been shown to improve medical condition in children bearing mitochondrial respiratory chain complex mutations,³⁵ we tested the possibility of reactivating thymopoiesis *in vivo* by eliminating the excess of ROS and feeding the dams with a high fat diet (HFD) in which the major source of energy changed from carbohydrates to fatty acids.³⁶ We first demonstrated that NAC treatment efficiently suppressed the excess of mitochondrial ROS in *AIF*^{-/-} thymocytes (Figure 7d). Moreover, the treatment of the dams with HFD and, more evidently, with NAC + HFD restored the normal generation of ATP in the *AIF*^{-/-} thymocytes of the newborns (Figure 7e and Supplementary Table 4a). Strikingly, compared to that observed in animals fed in a standard carbon diet, thymocyte development was significantly reestablished in the *AIF*^{-/-} newborns fed with a HFD: (i) HFD alone favored the generation of DP thymocytes (a mean of ~16 %) and (ii) a HFD+NAC combination allowed for a highly significant DP development (a mean of ~40 %) (Figure 7f and Supplementary Table 4b). These results confirm *in vivo* the functionality of the FAO metabolic reprogramming of the *AIF*^{-/-} thymocytes.

DISCUSSION

The mitochondrion acts as a metabolic hub that provides signals to direct the differentiation and fate of different immune cell subsets.^{1, 4, 37-40} In the present study, we show that AIF plays a critical role in determining the fate of hematopoietic cells. The loss of AIF triggers a mitochondrial endpoint, which results in pleiotropic effects on hematopoietic development, including BM aplasia, alterations in the development of the T-cell, B-cell, and erythroid lineages, and a DN1 thymopoiesis blockade. Our findings also reveal that, in cases of mitochondrial OXPHOS dysfunction, BM cells and thymocytes reprogram their metabolism towards anaerobic glycolysis and FAO, respectively (Figure 8). These metabolic changes are not directly related to the initiation of cell death processes (i.e., caspase activation).

In addition to its role in cell death,^{15-18, 20, 41} AIF is indispensable for OXPHOS function and mitochondrial energy production.^{11-13, 42-44} According to the “solid-state” model of ETC super-complex organization,^{31, 33} alterations on complex I assembly are sufficient to modify the architectural structure of the mitochondrial ETC and to yield OXPHOS dysregulation, along with respiratory defects, a reduced capacity for ATP production, and altered ROS generation; the same defects could be observed in *AIF*^{-Y} BM cells and thymocytes. Of note, AIF deficiency does not yield fully defective mitochondria: (i) the assessment of individual complex activities in *AIF*^{-Y} cells reveals a functional respiratory chain with oxygen as the final electron acceptor; (ii) ETC electron transport is still coupled to ATP synthesis; and (iii) the mitochondrial proteins CPT1 and ACADL appear implicated in the FAO performed by *AIF*^{-Y} thymocytes. These mitochondrial functionalities of the *AIF*^{-Y} cells appear to be critical for maintaining hematopoietic cell viability in neonatal mice and for yielding adaptive mitochondrial metabolic responses.

The role of AIF in the immune system was initially assessed in the Hq strain, which is not an AIF knockout mice.^{26, 27} Additionally, the mitochondrial role of AIF in the T- and B-cell lineages was analyzed more recently by using *Lck*-Cre and CD19-Cre mouse models.^{28, 45} A comparison between the immune alterations reported in these works and those characterizing the *AIF*^{-Y} model presented here indicates that the generation of *bona fide* hematopoietic AIF KO mice reveals a greater role for AIF in hematopoiesis. Specifically, thymocytes from Hq mice exhibited higher ROS levels, which appeared to be responsible for delayed DN3 development. By contrast, the T-cell developmental defects in our *AIF*^{-Y} mice were rather strong: DP cell generation was not delayed but, instead, was fully compromised and a blockade was observed in the DN stage, with DN1 accumulation and delayed DN2/DN3 and DN3/DN4 transitions. This

could be observed in fetuses, thus very early during thymic development. The analysis of the earliest thymic T lineage precursors reveals, among other signs, a progressive exhaustion of the DN1a/DN1b subsets that is concomitant to the hypocellularity of the CLP precursors detected in the BM. This suggests that the progressive loss of the canonical T precursors⁴⁶ is a consequence of BM perturbation. However, it seems that the DN1a/DN1b subsets of the *AIF*^{-Y} mice are still able to generate the DN2 population⁴⁶ that is always present in the thymus of the animals. Therefore, we could hypothesize that the delayed DN2/DN3 and DN3/DN4 transitions are independent from the canonical T precursors loss and, consequently, are associated to the OXPHOS/metabolic defaults caused by the AIF deficiency. This is in line with the results reported in the Harlequin mice model.^{26,27} In a more specific work, it would also be interesting to analyze in detail the consequences that low levels of the DN1c cells (which have the potential to generate cells expressing B lineage markers)⁴⁶ and the progressive accumulation of the less proliferative DN1e subset have for *AIF*^{-Y} mice. Overall, our results seem to indicate that the developmental defaults characterizing the *AIF*^{-Y} thymocytes (blockade at the DN stage) are cell intrinsic. The feeding of *AIF*^{-Y} dams with an HFD allows for the generation of DP thymocytes without necessarily provoking a rescue in the HSC and progenitors (Supplementary Figure 10). Thus, it seems that the change of energy source is enough for the existing thymocytes to progress towards a DP phenotype. As could be expected, protection against the deleterious ROS by NAC favors this development.

In contrast to our results (and the results reported in the Hq strain),^{26, 27} the immune alterations measured in the *Lck*-Cre model indicate that *Aif* ablation is associated with a loss in the number of peripheral T-cells without defects in thymocyte development.^{28, 45} In apparent opposition to these results, we observed that the early loss of AIF not only provoked a dramatic decrease in the number of T-cells in the peripheral organs, but also profound defects in thymopoiesis. This disagreement can be explained by the earlier elimination of AIF in our mice model compared to the latest *Aif* ablation in the *Lck*-Cre (around the DN3 stage). Indeed, the blockade at the DN stage observed in our *AIF*^{-Y} mice, with alterations in the DN1, DN2 and DN3 stages, cannot be detected in the *Lck*-Cre animals. Of note, the adjustment in the mitochondrial metabolism profoundly alters DN1-to-DN4 thymocyte development.^{9, 10} Remarkably, in contrast to previous results on Hq and CD19-Cre AIF KO mouse models,²⁶⁻²⁸ our findings originally indicated that the loss of AIF undoubtedly affected B-cell and erythrocyte development with increased frequencies of precursor B-cells in the BM and spleen, as well as increased frequencies of pro-erythroblasts I and basophilic erythroblasts II in the spleen. Here, the significant loss of T-

cells observed in our mice model could also be implicated in the delayed B-cell development, as reported in other mice models.⁴⁷

AIF deficiency leads to impaired survival of HSC and progenitor cells, resulting in exhaustion of the HSC pool, a reduced capacity to differentiate into colonies in methylcellulose assays, as well as an absence of cell-autonomous HSC repopulating potential *in vivo*. All these features appear to be a consequence of the high levels of ROS associated to the loss of AIF, as evidenced by: (i) measurements of mitochondrial ROS levels; (ii) CFU assays performed in the presence of NAC, which fully restored the capacity of *AIF*^{-/-} BM cells to develop into colonies; and, (iii) *in vivo* scavenging experiments leading to the rescue of LT-HSC, ST-HSC, and MPP cells. ROS are toxic products of oxidative metabolism, which are necessary for intracellular signal transduction but can impair cellular functions when present in excess.^{48, 49} The main way for HSC and progenitor cells to limit the excess of ROS is to favor anaerobic glycolysis over OXPHOS.^{1, 6} Accordingly, we observed an increased use of glycolysis in BM cells from *AIF*^{-/-} mice. In the presence of a ROS scavenger, this metabolic shift seemed to be crucial to the rescue of the LT-HSC, ST-HSC, and MPP cellularity observed in both *in vitro* and *in vivo* experiments. Indeed, BM cells seemed to be exclusively adapted to a carbon metabolism and, contrary to thymocytes, appeared unable to shift towards FAO (Supplementary Figure 10a). The rescue of the LT-HSC, ST-HSC, and MPP cells described in Figure 4g failed when changing the energy source from carbohydrates to fatty acids, a reaction observed even in the presence of a ROS scavenger (Supplementary Figure 10b). These results are in line with previous publications which, in similar feeding conditions, demonstrate that HFD causes decreased proliferation in LSK cells and a general suppression of progenitor cell populations in the BM.⁵⁰ In our case, the inability to use FAO by the HSC and progenitors makes the anti-oxidant protection irrelevant. Therefore, it would be interesting to know whether activation of the FAO is directly blocked in BM cells, or if these cells exclusively favor glycolysis because it is a more appropriate way to generate energy in the context of the BM microenvironment.

ROS scavenging is also beneficial for T-cell rescue in *AIF*^{-/-} mice, corroborating the previously reported detrimental role of uncontrolled mitochondrial ROS in thymocytes.^{51, 52} However, the increased levels of ROS appear to be only partially responsible for the failure of *AIF*^{-/-} thymocyte development. The developmental blockade characterizing these thymocytes also seems related to the lack of energy generated by these cells in a carbon environment. Surprisingly, the *AIF*^{-/-} thymocytes could reprogram their metabolism by enhancing their capacity to assimilate long chain fatty acids. Because AIF KO thymocytes remain in a DN immature state, we have confirmed this adaptive metabolic capacity by directly confronting the

DN thymocyte compartment of the WT and KO animals (Supplementary Figure 7). Seahorse assays, performed with a palmitate substrate in the absence/presence of Etomoxir, corroborated that the KO thymocytes are able to generate ATP from fatty acids via CPT1 enzymatic activity. As a result, the change of energy source from carbohydrates to fatty acids, combined with protection against the excess of ROS, significantly restores thymocyte development in *AIF*^{-/-} animals. These results confirm that, as reported in other models with ETC alterations, it is possible to generate ATP by FAO in OXPHOS “damaged” mitochondria.⁵³ In future studies, it would appear necessary to analyze whether other molecular pathways implicated in thymocyte metabolism reprogramming also play a role in our mouse strain (e.g., Akt activation has been linked to a blockade in the DN3-to-DN4 cell transition⁵⁴ and deletion of LKB1 results in accumulation of DN3 thymocytes and reduction in the number of thymocytes⁵⁵⁻⁵⁷).

Altogether, we have identified AIF as a new player that acts by fine-tuning the mitochondrial OXPHOS/metabolism in order to dictate the differentiation and fate of hematopoietic cells. We also revealed, in BM cells and thymocytes, the specific metabolic reprogramming associated to the dysfunction of the mitochondrial OXPHOS. It would be of interest to know whether similar phenomena occur in the immune cell compartments of patients suffering from mitochondriopathies or from leukemias. In any case, from a medical perspective, our data reveal potential therapeutic targets to regulate the immune responses in the context of autoimmunity, inflammation, or anti-tumor responses (e.g., by disrupting the mitochondrial metabolism via AIF or OXPHOS targeting).

MATERIALS AND METHODS

Mice

All mice were housed at the Cordeliers Center animal facility under strictly controlled, specific-pathogen-free conditions (agreement B75-06-12). Experiments were performed in accordance with ARRIVE ethical guidelines and with the approval of the French Ministry of Agriculture (agreement 1675). Mice were maintained with a rodent diet (R03, Scientific Animal Food & Engineering Diets) and water was made available *ad libitum* in a vivarium with a 12-h light-dark cycle at 22° C. In specific experiments, dams were fed on a standard control diet (CD; D12450J; Research Diets) or a high fat diet (HFD; D12492i; Research Diets) before mating and kept on the same diet during pregnancy and lactation.

To generate the hematopoietic cell-specific $AIF^{-/Y}$ mice, the exon 11 of *Aifm1* (*Pdcd8*, *Aif*) was flanked by LoxP sites using standard gene-targeting techniques (Supplementary Figure 1). After at least fifteen episodes of interbreeding in the C57BL/6J background, the *Aifm1^{fl/+}* females were crossed with C57BL/6J *Vav1-Cre* males (Jackson Laboratory) to obtain the $AIF^{-/Y}$ mice (*Aifm1^{fl/Y}*; *Vav1-Cre⁺*). The $AIF^{+/Y}$ littermates were used as control WT mice (defined as $AIF^{+/Y}$ in the manuscript). No significant differences were observed between the *Aifm1^{fl/Y}*; *Vav1-Cre⁻*, *Aifm1^{+/Y}*; *Vav1-Cre⁺*, *Aifm1^{+/Y}*; *Vav1-Cre⁻* genotypes. To generate the AIF-deficient mice in adult animals, the *Aifm1^{fl/+}* females were crossed to *Rosa26-CreERT2* males (provided by Dr. Anton Bernes, NCI, Amsterdam, The Netherlands)³⁰ and, ~3 months after birth, the *Aifm1^{fl/Y}*; *Rosa26-CreERT2⁺* animals were injected daily with tamoxifen (5 intra-peritoneal injections; 50 mg.kg⁻¹ body weight). The *Aifm1^{fl/Y}*; *Rosa26-CreERT2⁻* tamoxifen-injected mice were used as control (WT) animals. No significant differences were observed with the other non-AIF deleted genotypes generated by the crossing.

To perform the antioxidant treatment of the lactating mice, N-acetyl-L-cysteine NAC (Sigma) was administered to the dams in drinking water at 2g.kg⁻¹ of body weight per day (starting 3 days after giving birth and until newborn sacrifice). Mice peripheral blood samples were collected in EDTA-coated tubes and cell counts were analyzed in an automated counter (Scil Vet abc; SCIL GmbH).

Flow cytometry

For the different immunophenotyping approaches, the cellular suspensions from thymi, spleens, and BM were labeled with the corresponding antibody in FACS Buffer (2 mM EDTA 2% FCS PBS), recorded in a FACSCanto II (BD Biosciences), and analyzed using the FlowJo software

(TreeStar Inc). All flow cytometry samples were treated with FcBlock (2.4G2; BD Biosciences) prior to their incubation with primary antibodies, except when identifying the BM HSC subsets.

The following antibodies (clone) were used: CD44 (IM7), CD45R/B220 (RA3-6B2), CD34 (RAM34), CD127 (A7R34), CD3 ϵ -PE (145-2C11), Gr-1 (RB6-8C5), CD69 (H1-2F3), Foxp3 (FJK-16s), CD135 (Flt3) (A2F10), CD45.1 (A20), CD150 (SLAM) (TC15-12F12.2), CD24 (M1/69), $\gamma\delta$ T cells (GL3), CD4 (RM4-5), Ter119 (TER-119), F4/80 (BM8), streptavidin, Sca-1 (D7), TCR-b-chain, TC (GL3), CD11c (N418), CD62L (MEL-14), IgM (R6-60.2), CD71 (RI7217), CD34 (RAM34), CD4 (RM4-5), CD19 (ebio1D3), CD8 α (53-6.7), NK-1.1 (PK136), IgD (11-26c.2a), CD11b (M1/70), CD25 (PC61), CD117/cKit (2B8), CD16/32 (HM48-1). Antibodies were obtained from BioLegend, BD Biosciences, or eBioscience.

For detection of LT-HSC, ST-HSC, MPP, MEP, CMP, and GMP cells, BM cells were incubated with a cocktail of biotinylated antibodies against Mac-1 α (CD11b), Gr-1 (Ly-6G/C), Ter119, CD3, CD4, CD8a, and B220 (BD Biosciences) followed by detection with streptavidin conjugated to PerCP-Cy5.5. Then, cKit, Sca-1, CD34, CD135, and CD16/32 fluorochrome-conjugated antibodies were added to the mix. To define CLP cells and following a similar approach, cKit, Sca1, and CD127 fluorochrome-conjugated antibodies were added to the initial cocktail. For congenic strain discrimination, anti-CD45.1 and anti-CD45.2 antibodies (BD Biosciences) were used.

For the analysis of the DN compartment, thymocytes were incubated with a cocktail of biotinylated antibodies against CD8a, Mac-1 α (CD11b), Gr-1 (Ly-6G/C), Ter119, CD3, and B220 (BD Biosciences) followed by detection with streptavidin conjugated to PerCP-Cy5.5. Then, CD24, CD25, CD44, and cKit antibodies were added to the mix. DN1 subpopulations were defined as: DN1a (cKit+CD24^{low}), DN1b (cKit+CD24⁺), DN1c (cKit-CD24⁺), DN1d (cKit-CD24^{low}), and DN1e (cKit-CD24⁻).

Isolation of DN fraction was performed by negative selection. Briefly, thymocytes were pre-incubated with a mix of CD4 and CD8 magnetically labeled antibodies (BD Biosciences) and then placed on the BDTM IMag Cell Separation System, following the manufacturer instructions.

Mitochondrial and cellular analysis

For mitochondrial ROS, mitochondrial mass, and $\Delta\Psi_m$ measurements, cells were incubated with MitoSOX (5 μ M), Mitotracker Green and Mitotracker Red (100 nM each) (Invitrogen) respectively before assessment in a FACSCanto II.

For analysis of glucose uptake, BM cells and thymocytes were incubated (30 min; 37°C) in glucose-free DMEM with 2-NBDG (100 µM; Invitrogen) prior to flow cytometry assessment.

For DNA damage detection, cells were first labeled for HSC markers, incubated with a cytofix-cytoperm buffer (20 min on ice), and washed twice in Permwash buffer (BD Biosciences). Cells were then incubated with anti-γH2AX antibody (16-202A; Millipore) and analyzed in a FACSCanto II.

Apoptosis (cell death) was assessed by flow cytometry using Annexin-V-APC (0.1 µg/ml; BD Biosciences) and 7AAD double labeling (1 µg/ml; BD Biosciences). In some experiments, BM cells and thymocytes were pretreated during 30 min with the broad-spectrum caspase inhibitor Q-VD-OPh (QVD, 1 µM) before performing metabolic and cytometric tests.

ATP was analyzed in 10⁴ BM cells or thymocytes with an ATP bioluminescent kit (Abcam) in an Infinite M100 PRO plate reader (Tecan) and expressed as total ATP or ATP/ADP ratio.

For lactate measurement, cells were cultured for 2 h in a serum-free medium and centrifuged. Then, the supernatant was used to quantify extracellular L-lactate with a kit from Cayman Chemical Company in an Infinite M100 PRO plate reader (Tecan).

Metabolomic approach

The whole metabolomic assay was performed on 3x10⁷ BM cells by GC-TOF-MS on a LECO Pegasus III with an Agilent 6890N GC system (Massy, France) and an Agilent 7683 automatic liquid sampler as described⁵⁸. The column used was an RTX-5 w/integra-Guard (30 m, 0.25 mm internal diameter + 10 m integrated guard column) (Restek, Evry, France). Metabolites were extracted from samples using a methanol/water mixture (80/20 v/v). Peak identity was established by comparison of the fragmentation pattern with MS available databases (NIST), using a match cut-off criterion of 700/1000 and by retention time using the alkane series as retention standards. The integration of peaks was performed using the LECO Pegasus software (Garges-lès-Gonesse, France). The relative amount of each metabolite was calculated on the basis of the corresponding peak area compared with an internal standard (Ribitol).

Clark electrode

Oxygen consumption rates (OCR) were measured in 5x10⁷ BM cells as previously described.⁵⁹ Respiration was measured in non-permeabilized cells under basal conditions and in response to the sequential addition of oligomycin (10 µM), fluoro-carbonyl cyanide phenylhydrazone (FCCP; 5 µM), amytal (2 mM), and azide (5 mM).

Measurement of oxygen consumption rate (OCR), extracellular acidification rates (ECAR), fatty acid oxidation (FAO), and glutamine dependency by Seahorse

Bone marrow cells or thymocytes isolated from *AIF^{+/-Y}* and *AIF^{-/-Y}* animals were seeded at a density of 400,000 to 800,000 cells per well in an XFe96 cell culture microplate pretreated with CellTak (Corning). Cells were balanced for 1 h in unbuffered XF assay media (Agilent Technologies) supplemented for OCR analysis with either 2 mM Glutamine, 10 mM Glucose and 1 mM Sodium Pyruvate or just 2 mM Glutamine for ECAR measurement. For OCR measurements, compounds were injected during the assay at the following final concentrations: Oligomycin (ATP synthase inhibitor, 1 μ M), FCCP (uncoupling agent measuring the maximal respiration capacity; 1 μ M), Rotenone and Antimycin A (ETC inhibitors; 1 μ M). For ECAR measurements, Glucose (10 mM), Oligomycin (1 μ M) and 2-Deoxyglucose (2-DG, glycolytic inhibitor; 500 mM) were injected.

The activities of complex I, II/III and IV were measured in BM cells plated in mitochondria assay buffer (660 mM Mannitol, 210 mM Sucrose, 30 mM KH₂PO₄, 15 mM MgCl₂, 6 mM HEPES, 3 mM EGTA, 0.6% fatty acid free BSA) supplemented with 4 mM ADP and 1 nM XF Plasma Membrane Permeabilizer Reagent (XF PMP, Agilent Technologies). The complex I substrates (1 mM Malate and 10 mM Pyruvate), the complex II substrate (10 mM Succinate) or the complex IV substrates (100 μ M TMPD and 10 mM Ascorbate) were then added and OCR determined.

For FAO tests, cells were plated in FAO assay media (110 mM NaCl, 4.7 mM KCl, 1.25 mM CaCl₂, 2 mM MgSO₄, 1.2 mM NaH₂PO₄) supplemented with 2.5 mM Glucose, 0.5 mM Carnitine, and 5 mM HEPES. After measurements of basal OCR, BSA control (100 μ M), Palmitate-BSA FAO Substrate (17 μ M) (Agilent Technologies), or Etomoxir (200 μ M) were injected.

For the glutamine dependent assessment, BM cells were plated in unbuffered XF assay media (Agilent Technologies). Then, in ECAR measurements, Glucose (10mM), Glutamine (2 mM), or Glucose + Glutamine (10 mM and 2 mM, respectively) were injected followed by 2-DG (500 mM) inhibition. In the OCR assessment, Glutamine (2 mM) and BPTES (3 μ M) were sequentially injected.

High-resolution fluorescent in situ hybridization by RNAscope (FISH by RNAscope®)

RNAscope assessment was strictly performed following manufacturing procedures (Advanced Cell Diagnostics, inc.; ACD).³⁴ Briefly, thymocytes purified from *AIF^{+/-Y}* and *AIF^{-/-Y}* animals were fixed with 4 % paraformaldehyde for 30 minutes at 4°C, washed with PBS pH 7.2, centrifuged

(Cytospin 3, Shandon) at 700 rpm for 3 minutes on Superfrost®Plus slides, dehydrated and permeabilized by Protease III digestion (ACD) for 10 minutes at RT. Then, slides were hybridized with mouse Cpt1 (conjugated to Atto 550) and Peptidylprolyl Isomerase B (Ppib, conjugated to Alexa 488; mRNA control) probes. Nuclei were visualized using DAPI staining. Hybridization of a probe against the *Bacillus subtilis* dihydrodipicolinate reductase (DapB) gene was used as a negative control. The resulting hybridized slides were imaged using a LSM 710 Zeiss confocal microscope and analyzed using the image J software. RNAscope experiments were repeated three times on different slide sets with similar results.

Retroviral transduction in BM and FL cells

Murine AIF cDNA was cloned into the MSCV-IRES-GFP retroviral vector. Viruses were generated into 293T cells by X-tremeGene 9 (ROCHE) transient transfection of the retroviral constructs and the packaging plasmids EcoPack/Psi Eco. 48 h post-transfection, retroviral supernatants were harvested, clarified by filtration, and kept at -80°C until use. For transduction in colony-forming assays and FL *in vivo* transfer, *AIF*^{+/*Y*} or *AIF*^{-/*Y*} donor embryos were collected at E15.5 and FL cells were prepared and seeded. For transduction in colony-forming assays, BM *AIF*^{+/*Y*} or *AIF*^{-/*Y*} cells were obtained from 7-day-old animals and prepared similarly to the FL cells. After an overnight culture in RPMI 1640 supplemented with 10% FBS, 10 ng/mL mIL-3, 10 ng/mL mIL-6, and 10ng/mL mSCF, cells were spin-infected with either MSCV-IRES-GFP or MSCV-mAIF-IRES-GFP viral supernatants. Then, cells were plated in M3434 methylcellulose medium or transferred in recipient mice CD45.1 as described below. Note that the percentage of cell transduction is similar in FL and BM cells (~5 %).

Transplantation assays

CD45.1 C57Bl/6J mice were lethally irradiated and reconstituted by retro-orbital injections with BM, LSK, or FL cells from *AIF*^{-/*Y*} or *AIF*^{+/*Y*} CD45.2 animals collected between 3 and 10 days after mice birth (BM and LSK) or between E12.5 and E15.5 (FL cells). In non-competitive experiments, 1×10⁶ BM CD45.2 donor cells were injected in CD45.1 mice. In competitive assays, 1×10⁴ CD45.2 donor LSK cells were mixed with 2.5×10⁵ CD45.1 competitor BM cells before injection. In the rescue performed with FL cells transduced or not with the mAIF cDNA, 2×10⁶ FL CD45.2 cells were mixed with 1×10⁶ CD45.1/CD45.2 BM cells before injection in CD45.1 mice. Engraftment in the immune organs in non-competitive and competitive transplantation assays with BM and LSK cells was assessed by CD45.2 donor contribution using FACS analysis of peripheral blood samples at 2 and 6 weeks post-transplantation and at the moment of sacrifice (8 weeks) in the immune organs. In competitive experiments with FL

transduced cells, samples were analyzed at 1 and 3 months post-engraftment in the peripheral blood and at 4 months post-engraftment in the BM. In each experiment, transplants were carried out with five donors per genotype and with, at least, five recipient mice per donor.

CFU assays

Whole FL cells or BM cells were plated in duplicate in MethoCult M3434 (StemCell Technologies) and cultured at 37°C in 5% CO₂ for 10 days before colony counting. Colonies were scored according to morphological criteria.⁶⁰ In selected experiments, NAC (250 μM) was added to methylcellulose at the time of cell plating.

Electron microscopy

BM cells or thymocytes were centrifuged (10 min; 300g) and the resulted pellets were fixed at 4° C for 2 h in 2.5% glutaraldehyde in 0.1 M phosphate buffer (pH 7.3), postfixed for 1 h in 1% buffered osmium tetroxide, dehydrated through a graded ethanol series, and embedded in Epon 812. The ultrathin sections were counterstained with 2% aqueous uranyl acetate for 30 min, then with lead citrate for 10 min and finally viewed under a Philips 100X electron microscope.

Immunoblotting

Freshly isolated BM, spleen, thymus, and FL cells were lysed in buffer containing 50 mM Tris pH 7.5, 150 mM NaCl, 1 mM EDTA, 1% Triton X-100, and the protease/phosphatase inhibitor cocktail from Roche. Protein concentration was determined using the BioRad Protein Assay. Equal amounts of total proteins (50 μg) were loaded on linear SDS-PAGE gels and transferred onto a PVDF or nitrocellulose membrane. Membrane blocking and antibody incubations were performed in TBS 0.1% Tween 20 plus 5% non-fat dry milk. The primary antibodies used were: AIF (D-20, Santa Cruz), NDUFA9 (20C11B11B11, Life technologies), SDHA (2E3GC12FB2AE2, Life technologies), UQCRC2 (13G12AF12BB11, Abcam), COX4I2 (20E8C12, Abcam), ATP5B (3D5AB1, Life technologies), VDAC1 (ab15895, Abcam), and β-actin (AC15, Sigma). Immunoreactive proteins were detected using HRP-conjugated secondary antibodies and visualized with SuperSignal West Dura chemiluminescence kits (Thermo Scientific). Immunoblot images were acquired on a MF-ChemiBIS 4.2 (DNR Bio-Imaging Systems). AIF, NDUFA9, SDHA, UQCRC2, COX4I2, and ATP5B protein expression were quantified using the Multi Gauge 3.0 software (Fujifilm Life Sciences). The optical density was normalized according to an endogenous background and the OD mean of *AIF*^{-Y} ETC proteins was expressed as a percentage relative to the OD mean obtained in the proteins from *AIF*^{+Y} cells (= 100 %).

Quantitative RT-PCR

Total RNA was extracted using the Nucleospin® RNA II kit (Macherey-Nagel). cDNA was prepared using Superscript® II reverse transcriptase (Life Technologies). Quantitative RT-PCR was performed using the TaqMan® Gene Expression Assays (Life Technologies) for *Pgc1α* (Peroxisome proliferator-activated receptor gamma coactivator 1-alpha), *Cpt1* (carnitine palmitoyltransferase I), *Acadl* (Acyl-CoA Dehydrogenase, Long Chain), or *Pdk4* (pyruvate dehydrogenase kinase, isozyme 4). PCR reactions were performed in duplicate using TaqMan® Fast advanced Master Mix (Life Technologies). The products were amplified in a ViiA7 Real-time PCR System (Life Technologies) at 60°C for 40 cycles. Data were analyzed using the comparative threshold cycle method. The housekeeping expression of *18S* was utilized to normalize the data.

Histology

Femurs were fixed in 4% PFA and embedded in paraffin, and 4 μm thick sections were stained with hematoxylin-eosin. Images were obtained using an Olympus AX70 microscope and a Sony XCD-U100CR color digital camera. The microscope was equipped with a 10X/0.30 objective lens. All images were acquired using the Archimed software (Microvision Instrument) and analyzed using Adobe Photoshop 8.0.1 (Adobe Systems).

Statistics

Results, displayed as mean ± SEM, were statistically analyzed using the GraphPad Prism software. Kaplan–Meier curves were produced and analyzed by log-rank tests. Statistically significant p values were indicated as follows: * $p \leq 0.05$, ** $p \leq 0.01$, *** $p \leq 0.001$, **** $p \leq 0.0001$. All the experiments were independently repeated at least three times. In the metabolomic assessment, the biostatistic analysis was performed with the Mev software (<http://www.tm4.org/mev/>) and the statistical significance was calculated using Student's t test. For the hierarchical clustering analysis, the data were normalized using the following formula: $Normalized\ value = [(Value) - Mean(Row)] / [Standard\ deviation(Row)]$.

ACKNOWLEDGMENTS

We thank G. Delespesse, M. Rubio, K. Wakahara, and N. Baba (CRCHUM, Montréal, Canada) for support and helpful tips and discussions, Sophie Ezine and Victoria Michaels (INEM UMR-S1151, CNRS UMR 8253 Université Paris Descartes-Site Broussais, Paris, France) for invaluable help in thymocyte labeling and flow cytometry analysis, the animal facility staff (CEF Cordeliers, Paris, France) for mice housing support, Christophe Klein for help in confocal image acquisition (CICC, Cordeliers, Paris, France), V. Della Valle and D. Roos-Weil (U1170

INSERM, Villejuif, France) for advice in transplantation and colony-forming assays, A. Prola and C. Lemaire (UMRS 1180, Châtenay-Malabry, France) for help in the set-up of Clark electrode oxygen consumption assays and for providing amytal, and M. Segade (Houston, US) for proofreading. This work was supported by Fondation ARC (PJA20151203407), Ligue Contre le Cancer-Comité de Paris (RS15/75-63 and RS16/75-50), Association Laurette Fugain (ALF 15/09), Fondation de France-Comité Cancer, Fondation pour la Recherche Médicale, French National Research Agency (ANR-09-BLAN-0247 and ANR-12-EMMA-0045), and French National Cancer Institute (INCa-5839) (to SA Susin). L.C. received PhD fellowship support from ENS-Cachan, Société Française d'Hématologie, and Fondation ARC, as well as travel grants from Boehringer Ingelheim and Journal of Cell Science. A.B. received PhD fellowships from the French Research Ministry and Société Française d'Hématologie.

AUTHOR CONTRIBUTIONS

L.C. and A.B. designed experiments, performed *in vitro* and *in vivo* studies, interpreted the data, and helped to write the manuscript. M.-N.B.-N., L.S., L.D., L.V., and M.B., performed *in vitro* and/or *in vivo* experiments. I.N. designed and performed the Seahorse metabolic assessment. C.L. performed histological analyses. K.G. and D.C. carried out electron microscopy. F.G., performed metabolomic approach. V.Q.V., M.S., T.M., and O.A.B. provided reagents, analyzed data, and/or contributed to the experimental design and analysis. S.A.S. supervised the study, designed experiments, interpreted the data, and wrote the manuscript.

CONFLICT OF INTEREST

The authors declare no conflict of interest.

FIGURE LEGENDS

Figure 1. AIF loss led to pancytopenia and hematopoietic developmental defects. (a) *Left*, representative images of $AIF^{+/Y}$ and $AIF^{-/Y}$ mice. $AIF^{-/Y}$ 28-day-old animals present external signs of anemia in fingers and tail (arrows). *Middle and right*, H/E staining of BM and overall thymus size observed in $AIF^{+/Y}$ and $AIF^{-/Y}$ mice at the indicated time after birth. (b) Kaplan-Meier survival probability of $AIF^{+/Y}$ and $AIF^{-/Y}$ mice. (c) Kinetic cell count of white blood cells (WBC), red blood cells (RBC), and platelets from $AIF^{+/Y}$ and $AIF^{-/Y}$ mice (n = 10 mice per group). (d) Kinetic assessment of cellularity in BM, spleen, thymus, and lymph nodes from $AIF^{+/Y}$ and $AIF^{-/Y}$ mice (n = 10 mice per group). (e) Number of BM erythroid ($Ter119^+$), granulocytic ($CD11b^+Gr1^+$), macrophagic/monocytic ($CD11b^+Gr1^-$), B-cells ($B220^+$), and T-cells ($CD3^+$) measured in 7 to 28-day-old $AIF^{+/Y}$ and $AIF^{-/Y}$ mice (n = 8 mice per group). (f) Percentages of $CD4^+/CD8^-$ (DN), $CD4^+/CD8^+$ (DP), $CD4^+$, and $CD8^+$ thymocytes recorded in 21-day-old $AIF^{+/Y}$ and $AIF^{-/Y}$ mice (n = 10 mice per group). (g) *Left*, Flow cytometry panels of IgD/IgM staining on B220-expressing BM and spleen cells from 21-day-old $AIF^{+/Y}$ and $AIF^{-/Y}$ animals. *Right*, frequencies of precursor (IgM^-IgD^-), immature (IgM^+IgD^-), transitional (IgM^+IgD^{int}), and mature (IgM^+IgD^+) B220⁺ B-cells from 21-day-old $AIF^{+/Y}$ and $AIF^{-/Y}$ mice (n = 14 mice per group). (h) Percentages of pro-erythroblasts I ($CD71^+Ter119^{int}$), basophilic erythroblasts II ($CD71^+Ter119^+$), late basophilic and chromatophilic erythroblasts III ($CD71^{int}Ter119^+$), and orthochromatic erythroblasts IV ($CD71^-Ter119^+$) assessed in 21-day-old $AIF^{+/Y}$ and $AIF^{-/Y}$ mice (n = 6 mice per group). Statistical significance was calculated by Mann Whitney test. Symbols and bars represent mean \pm SEM.

Figure 2. AIF loss induced OXPHOS dysfunction, ROS generation, and broad metabolic adjustments in BM cells. (a) Representative immunoblot of BM cells obtained from $AIF^{+/Y}$ and $AIF^{-/Y}$ 21-day-old animals revealing AIF and key proteins of the ETC complexes. VDAC1 was used as mitochondrial loading marker. Equal cellular loading was confirmed by β -actin probing (n = 3 independent experiments with similar results). (b) Representative electron micrographs of $AIF^{+/Y}$ and $AIF^{-/Y}$ BM cells. The black arrows mark the mitochondria. Bar: 0.5 μ m. (c) *Left*, OCR of $AIF^{+/Y}$ and $AIF^{-/Y}$ BM cells under basal conditions (initial rates) and in response to sequential treatment with Oligomycin, FCCP, and Rotenone/Antimycin A. Arrows indicate the time of the addition of each reagent. *Right*, Basal and maximal OCR of BM cells expressed as a histogram (n = 3 independent experiments). (d) $\Delta\Psi_m$ assessment performed in $AIF^{+/Y}$ and $AIF^{-/Y}$ BM cells (n = 8 mice per group). (e) Mitochondrial ROS levels recorded in $AIF^{+/Y}$ and $AIF^{-/Y}$ BM cells (n = 8 mice per group). (f) *Left*, Mitochondrial mass of $AIF^{+/Y}$ and $AIF^{-/Y}$ BM cells assessed by

Mitotracker Green labeling (n = 8 mice per group). *Right*, PGC1a mRNA levels determined by qPCR in $AIF^{+/Y}$ and $AIF^{-/Y}$ BM cells (n = 5). The 18S mRNA expression was used to normalize data. **(g)** Glucose uptake measured by the assimilation of 2-NBDG in $AIF^{+/Y}$ and $AIF^{-/Y}$ BM cells (n = 10 mice per group). **(h)** *Left*, ECAR of $AIF^{+/Y}$ and $AIF^{-/Y}$ BM cells measured in response to sequential addition Glucose, Oligomycin, and 2-deoxyglucose (2-DG). Arrows indicate the time of the addition of each reagent. *Right*, ECAR of BM cells after Glucose treatment expressed as a histogram (n = 3 independent experiments). **(i)** Lactate release analyzed in $AIF^{+/Y}$ and $AIF^{-/Y}$ BM cells (n = 7 mice per group). **(j)** Heat map showing relative levels and hierarchical clustering of the indicated metabolite detected in BM cells. Each column corresponds to a different $AIF^{+/Y}$ or $AIF^{-/Y}$ animal and the color of the cell indicates the relative content of the metabolite (from green to red). Upon comparison to $AIF^{+/Y}$ cells, only metabolites showing a significant modification in the $AIF^{-/Y}$ cells were represented. **(k)** ATP levels recorded in $AIF^{+/Y}$ and $AIF^{-/Y}$ BM cells (n = 8 mice per group). Statistical significance was calculated by Mann Whitney test. Bars represent mean \pm SEM. All tests were performed in 21-day-old animals.

Figure 3. Mitochondrial OXPHOS dysfunction associated with AIF loss generated cell exhaustion and alteration in the repopulating potential of hematopoietic progenitors. **(a)** *Left*, Identification of LSK (Lin⁻Sca-1⁺ Kit⁺) cells in fetal liver (E17.5) or BM from 7-, 14-, 21-, and 28-day-old $AIF^{+/Y}$ and $AIF^{-/Y}$ animals by flow cytometry. Numbers are the percentages of LSK cells. *Right*, The number of LSK cells was recorded and graphed either as a percentage of total cells in the BM or as a number of cells (cellularity) (n = 5 mice per group). **(b)** Number of LT-HSC, ST-HSC, MPP, CLP, CMP, GMP, and MEP cells in 7- to 28-day-old animals (n = 5 mice per group). **(c)** Fetal liver cells (FL; E15.5) or BM cells from 7 or 21-day-old animals were seeded in methylcellulose culture and colonies formed by the GEMM, GM, or single lineages (G, M, and E) were counted (n = 8 independent experiments). **(d)** The effects of AIF re-expression on the colony-forming capacities were tested with E15.5 FL cells from $AIF^{+/Y}$ and $AIF^{-/Y}$ embryos transduced with the retroviral MSCV-IRES-GFP (empty) or MSCV-mAIF_{WT}-IRES-GFP (mAIF WT) vectors. Colonies were counted as in **(c)** (n = 3 independent experiments). The expression of AIF and the complex I subunit NDUFA9 was verified by immunoblotting. Equal loading was confirmed by β -actin probing. **(e)** In non-competitive transplantation experiments, CD45.2 donor BM cells from 7-day-old $AIF^{+/Y}$ and $AIF^{-/Y}$ mice were transplanted into irradiated CD45.1 recipient animals. CD45.2 chimerism in recipient mice was evaluated at the indicated time after transplantation (n = 5 mice per group). **(f)** In competitive transplantation experiments, CD45.2 donor LSK cells from 7-day-old WT or AIF KO animals

were transplanted into irradiated CD45.1 mice along with recipient BM cells. CD45.2 chimerism in recipient mice was assessed at 2, 6, and 8 weeks after transplantation (n = 5 mice per group). **(g)** The effects of mAIF re-expression on hematopoietic reconstitution were tested with E15.5 FL cells from $AIF^{+/Y}$ and $AIF^{-/Y}$ embryos transduced with the retroviral MSCV-IRES-GFP (Empty) or MSCV-mAIF_{WT}-IRES-GFP (mAIF WT) vectors (n = 6 mice per group). Statistical significance was calculated by Mann Whitney **(a, b, c, e, f, and g)** or two-way ANOVA **(d)** tests. Symbols and bars represent mean \pm SEM.

Figure 4. High levels of ROS in the $AIF^{-/Y}$ HSC and progenitor cells provoked DNA damage and apoptosis. **(a)** *Left*, ECAR of $AIF^{+/Y}$ and $AIF^{-/Y}$ HSC and progenitors cells measured in response to sequential addition Glucose, Oligomycin, and 2-deoxyglucose (2-DG). Arrows indicate the time of the addition of each reagent. *Right*, ECAR of HSC and progenitor cells after Glucose treatment expressed as a histogram (n = 3 independent experiments). **(b-d)** Mitochondrial ROS generation (MitoSOX labeling) **(b)**, DNA damage (γ H2AX levels) **(c)**, and cell death (Annexin-V/7AAD co-staining) **(d)** were evaluated in $AIF^{+/Y}$ and $AIF^{-/Y}$ LT-HSC, ST-HSC, MPP cells from 7-day-old mice. Data are the fold change recorded in the $AIF^{-/Y}$ cells relative to the basal levels of the $AIF^{+/Y}$ cells (n = 5 mice per group). **(e)** Mitochondrial ROS levels measured by flow cytometry in $AIF^{+/Y}$ and $AIF^{-/Y}$ BM cells in the presence or absence of NAC (n = 6 mice per group). **(f)** Colony counting of BM $AIF^{+/Y}$ or $AIF^{-/Y}$ cells plated in methylcellulose in the presence or absence of NAC (n = 5 independent experiments). Representative images of the morphology of the different colonies are shown. **(g)** Dams were supplied or not with NAC in drinking water and the number of LT-HSC, ST-HSC, and MPP cells from 21-day-old $AIF^{+/Y}$ and $AIF^{-/Y}$ newborn mice was counted (n = 7 mice per group). Statistical significance was calculated by Mann Whitney **(a-e and g)** or two-way ANOVA **(f)** tests. Bars represent mean \pm SEM.

Figure 5. Mitochondrial AIF loss led to the blockade of thymopoiesis at a DN immature state. **(a)** *Left*, Gating strategy. *Right*, Cytometric identification of DN1-DN4 subsets of $AIF^{+/Y}$ and $AIF^{-/Y}$ embryos (E15.5 and E17.5) and 7-, 21-, and 28-day-old neonates (n = 7 embryos/mice per group). **(b)** *Left*, Gating strategy. Flow cytometry assessment of the DN1 prothymocyte compartment from 7- and 21-day-old $AIF^{+/Y}$ and $AIF^{-/Y}$ mice (n = 6 animals per group). **(c)** Frequency TCR β chain positive DN thymocytes measured in $AIF^{+/Y}$ and $AIF^{-/Y}$ 21-day-old animals (n = 8 mice per group). Statistical significance was calculated by Mann Whitney test. Bars represent mean \pm SEM.

Figure 6. AIF deficiency induced mitochondrial alterations and a significant drop in the cellular ATP levels in thymocytes. (a) Representative electron micrographs of $AIF^{+/Y}$ and $AIF^{-/Y}$ thymocytes. The black arrows mark the mitochondria. Bar: 0.5 μm . (b) *Left*, OCR of $AIF^{+/Y}$ and $AIF^{-/Y}$ thymocytes under basal conditions (initial rates) and in response to sequential treatment with Oligomycin, FCCP, and Rotenone/Antimycin A. Arrows indicate the time of the addition of each reagent. *Right*, Basal and maximal OCR of thymocytes expressed as a histogram (n = 3 independent experiments). (c) $\Delta\Psi\text{m}$ assessment in $AIF^{+/Y}$ and $AIF^{-/Y}$ 21-day-old animals (n = 18 mice per group). (d) Mitochondrial ROS levels measured in thymocytes from $AIF^{+/Y}$ and $AIF^{-/Y}$ 21-day-old animals (n = 18 mice per group). (e) Mitochondrial mass of $AIF^{+/Y}$ and $AIF^{-/Y}$ thymocytes from 21-day-old animals (n = 18 mice per group). (f) Glucose uptake measured by the assimilation of the D-glucose analogue 2-NBDG in $AIF^{+/Y}$ and $AIF^{-/Y}$ thymocytes from 21-day-old mice (n = 5 mice per group). (g) ATP levels recorded in $AIF^{+/Y}$ and $AIF^{-/Y}$ thymocytes from 21-day-old animals (n = 20 mice per group). Statistical significance was calculated by Mann Whitney test. Bars represent mean \pm SEM.

Figure 7. Mitochondrial OXPHOS breakdown favored fatty acid metabolism reprogramming in thymocytes. (a) CPT1, ACADL, and PDK4 mRNA levels determined by qPCR in $AIF^{+/Y}$ and $AIF^{-/Y}$ thymocytes from 21-day-old animals (n = 10 mice per group). The 18S mRNA expression was used to normalize the data. (b) RNAscope[®] fluorescent detection of Cpt1 α expression in representative $AIF^{+/Y}$ and $AIF^{-/Y}$ thymocytes from 21-day-old animals. Cpt1 mRNA transcripts were stained with a specific probe conjugated to Atto 550 (red) and nuclei were counterstained with DAPI (blue). Ppib expression, detected with a specific probe conjugated to Alexa 488 (green), was used as a control. Phase contrast analysis was used to visualize cells. Compared to the similar expression of Ppib in $AIF^{+/Y}$ and $AIF^{-/Y}$ thymocytes, CPT1 was over-expressed in $AIF^{-/Y}$ cells (n = 3 independent experiments with similar results). (c) *Left*, OCR was measured in thymocytes from $AIF^{+/Y}$ and $AIF^{-/Y}$ 21-day-old animals. After measurement of basal OCR, the FAO substrate Palmitate-BSA (17 μM) (Agilent Technologies) was injected and OCR was assessed during 60 min. Arrows indicate the time of Palmitate-BSA addition. *Right*, OCR was measured in thymocytes from $AIF^{-/Y}$ 21-day-old animals. After measurement of basal OCR, BSA control (blue line) or Palmitate-BSA FAO Substrate (17 μM) (red line) were injected followed by 200 μM Etomoxir addition to inhibit FAO. Arrows indicate the time of the injection of each reagent. OCR experiments were repeated three times with similar results. (d) Mitochondrial ROS levels measured in $AIF^{+/Y}$ and $AIF^{-/Y}$ thymocytes from 21-day-old newborns from dams supplied or not with NAC in drinking water (n = 9 animals per

group). (e) Total ATP levels of $AIF^{+/Y}$ and $AIF^{-/Y}$ thymocytes from 21-day-old newborns from dams fed with standard control diet or high-fat diet (HFD) and supplied or not with NAC in drinking water (n = 9 animals per group). (f) *Left*, percentage of CD4⁻/CD8⁻ (DN) and CD4⁺/CD8⁺ (DP) thymocytes in 21-day-old $AIF^{+/Y}$ and $AIF^{-/Y}$ newborns from dams fed as in (e) (n = 9 animals per group). The statistical analysis refers to the comparison between the percentage of DN or DP thymocytes recorded in the $AIF^{-/Y}$ newborns from dams fed in standard conditions and the percentage of DN or DP thymocytes recorded in $AIF^{-/Y}$ newborns from dams supplied either with NAC, HFD, or both. *Right*, representative flow cytometry panels of a CD4/CD8 labeling in $AIF^{-/Y}$ thymocytes from mice animals fed with a standard control diet ($AIF^{-/Y}$) or with an HFD supplied with NAC ($AIF^{-/Y}$ NAC + HFD). Statistical significance was calculated by Mann Whitney test. Bars represent mean \pm SEM.

Figure 8. Schematic representation of the consequences of the early *Aif* ablation in the hematopoietic cells. The loss of AIF in the hematopoietic cells resulted in a defective mitochondrial OXPHOS that was characterized by $\Delta\Psi_m$ loss, high ROS generation, and drop in ATP levels. These alterations provoke pleiotropic consequences in neonatal and adult $AIF^{-/Y}$ mice, including a progressive pancytopenia and T-cell, B-cell, and erythroid developmental defaults. BM cells and thymocytes utilize different adaptive metabolic mechanisms: BM cells counterbalance the AIF-mediated OXPHOS dysfunction by the stimulation of mitochondrial biogenesis and a shift towards anaerobic glycolysis, whereas thymocytes favor the fatty acid metabolism.
