(Received 10 July 2019; revised manuscript received 10 January 2020; accepted 31 January 2020; published 10 March 2020)

The coherence of electron spin qubits in semiconductor quantum dots suffers mostly from low-frequency noise. During the past decade, efforts have been devoted to mitigate such noise by material engineering, leading to substantial enhancement of the spin dephasing time for an idling qubit. However, the role of the environmental noise during spin manipulation, which determines the control fidelity, is less understood. We demonstrate an electron spin qubit whose coherence in the driven evolution is limited by high-frequency charge noise rather than the quasistatic noise inherent to any semiconductor device. We employ a feedback-control technique to actively suppress the latter, demonstrating a π -flip gate fidelity as high as $99.04 \pm 0.23\%$ in a gallium arsenide quantum dot. We show that the driven-evolution coherence is limited by the longitudinal noise at the Rabi frequency, whose spectrum resembles the $1/f$ noise observed in isotopically purified silicon qubits.

I. INTRODUCTION: NOISE IN SPIN QUBITS

Since electrical manipulation of a single spin was demonstrated in semiconductor quantum dots [1], enormous efforts have been devoted to improve spin coherence by controlling [2,3] or eliminating [4–6] nuclear spins, a

magnetic noise source inherent to the host material [7–9]. The progress is impressive: For example, dephasing times of $120 \mu\text{s}$ in ^{28}Si and $2 \mu\text{s}$ in GaAs have been demonstrated [4,10]. It is natural to expect that prolonging the spin coherence also improves the qubit control fidelity. However, while the spin coherence is dominated by low-frequency (quasistatic) noise, the control fidelity of a qubit is often impeded by noise at higher frequencies [11–14]. The underlying relationship between the control fidelity and spin coherence remains elusive, because there are different noise sources that could dominate in different frequency ranges, such as nuclear spin diffusion and charge fluctuators (see Fig. 1). The former shows a $1/f^\beta$ spectrum with $3 > \beta > 1$ in GaAs [15,16] and possibly in natural Si devices [17], while the latter with $\beta \sim 1$ can dominate in ^{28}Si devices [6]. In general, the dominant noise source depends on the material and structure of the quantum dot device as well as the frequency range of interest. To understand the limits on the qubit control fidelity imposed by those different mechanisms, we build a feedback-controlled circuit which implements realtime Hamiltonian estimation [10]. It allows us to suppress the low-frequency noise [18] and resolve the $1/f$ charge and nuclear spin noise at high frequencies. We analyze how the low-frequency and high-frequency parts of the noise compete with each other and discuss the limitations of the high-fidelity control.

FIG. 1. Example of noise power spectra for spin qubits with and without feedback. A typical noise spectrum composed of $1/f^2$ and $1/f$ noise is shown in a log-log plot (black line). The feedback control acts like an active filter suppressing the low-frequency noise (red line). Shown on the bottom are relevant frequencies with Δt the feedback latency, t the qubit evolution time at which the coherence is evaluated, and f_{rabi} the Rabi frequency.

II. DEVICE AND EXPERIMENTAL SETUP

We use a triple quantum dot (TQD) device fabricated on a GaAs/AlGaAs heterostructure wafer. An electron is confined in each quantum dot (QD) by the electrostatic potentials induced by Ti/Au gate electrodes. A Co micromagnet is placed on the surface and magnetized by a magnetic field of $B_{\text{ext}} = 1.01$ T applied in the z direction [see Fig. 2(a)], creating an inhomogeneous magnetic field over the QD array. The single-electron spin qubit reported in this work is located in the middle QD and manipulated by the electric-dipole spin resonance (EDSR) [19–21]. It is initialized and measured using the ancilla electron spin in the right QD [22] [see Fig. 2(b)]. An up-spin state of the qubit is prepared by initializing a doubly occupied singlet ground state in the right QD and loading one of the electrons to the middle QD. The voltage ramp is chosen to be adiabatic with respect to the interdot tunnel gap and the local magnetic field difference between the two dots but nonadiabatic with respect to the hyperfine gap. The final state is read out by unloading an up-spin state to the right QD in the reverse process while leaving a down-spin state blocked in the middle QD. The experiment is conducted in a dilution refrigerator with an electron temperature of 120 mK.

We first perform a standard Rabi measurement [22] to roughly identify the Rabi frequency f_{rabi} and the qubit resonance frequency $f_{\text{qubit}} = |g\mu_B B_{\text{total}}|/h$. Here, g is the electron g factor, μ_B is the Bohr magneton, and B_{total} is the sum of B_{ext} and the z components of the Overhauser field B_z^{nuc} and the micromagnet stray field B_z^{MM} . After that, we measure Ramsey oscillations using two $\pi/2$ microwave bursts of duration $(4f_{\text{rabi}})^{-1}$ separated by a time interval t_R . The lower panel in Fig. 2(c) shows the data gathered over 1200 s with a fixed microwave frequency

of $f_{\text{MW}} = 5.55$ GHz. The frequency of the measured oscillations fluctuates around a mean value $f_{\text{MW}} - f_{\text{qubit}} \approx 55$ MHz. The fluctuations arise from changes of B_z^{nuc} due to nuclear spin diffusion [24], leading to inhomogeneous broadening of f_{qubit} . Averaging all the measured data results in damped oscillations shown in the upper panel in Fig. 2(c). Fitting it with a Gaussian envelope gives a spin dephasing time of $T_2^* = 28.4$ ns.

III. THE FEEDBACK PROTOCOL

To suppress this dephasing, rooted in slow fluctuations [7] (quasistatic noise) of f_{qubit} , we employ a feedback-control scheme based on the realtime Hamiltonian estimation [25,26] [see Fig. 2(d)]. A similar technique was previously adopted for singlet-triplet qubits [10] to evaluate the stability of the idle qubit frequency, expressed by the dephasing time T_2^* , and its improvement upon noise estimation. Here, we apply this technique to a single spin. The difference from a singlet-triplet qubit first of all requires changes in the protocol details, as given below. Second, the noise field couples to the spin differently, through its local value rather than its spatial gradient. However, the most important difference is that we focus here on the stability of the qubit being driven rather than sitting idle. The rest of this section describes the details of the feedback protocol and its benchmarking, by examining how it boosts the dephasing time T_2^* . Readers interested solely on its benefits for the driven qubit stability can proceed directly to the next section.

The feedback scheme alternates the probe and target steps. In the former, the qubit frequency is probed by sampling 150 up- or down-spin outcomes of a Ramsey oscillation with $t_R = 2, 4, \dots, 300$ ns using $f_{\text{MW}} = f_{\text{qubit}}^{\text{est}} + \Delta_p$. Here, $f_{\text{qubit}}^{\text{est}}$ is the result of the qubit frequency estimation in the preceding probe step, and $\Delta_p = 50$ MHz is a fixed frequency offset inserted to ensure $f_{\text{MW}} > f_{\text{qubit}}$. With these settings, we use a Bayesian algorithm to estimate the instantaneous frequency detuning: $\delta f = f_{\text{qubit}} - f_{\text{qubit}}^{\text{est}}$. At the end of the probe step, the value of $f_{\text{qubit}}^{\text{est}}$ is updated to $f_{\text{qubit}}^{\text{est}} \mapsto f_{\text{qubit}}^{\text{est}} + \delta f$, and the microwave frequency is set to $f_{\text{MW}} = f_{\text{qubit}}^{\text{est}} + \Delta$. The subsequent target step begins after a short delay (approximately milliseconds) to stabilize the signal output. The variable Δ is a controllable offset such that $\Delta = 0$ corresponds to the target algorithm executed with f_{MW} equal to f_{qubit} . By continuously looping the probe-target sequence, we can compensate low-frequency fluctuations of f_{qubit} and remove their contribution to various qubit errors. For example, the dephasing time T_2^* is expected to be boosted by employing such a compensation protocol.

We now evaluate the performance of the feedback control by executing in the target step a Ramsey measurement similar to the one in the probe step ($\Delta = \Delta_p = 50$ MHz). Figure 3(a) shows the values of δf obtained from Ramsey

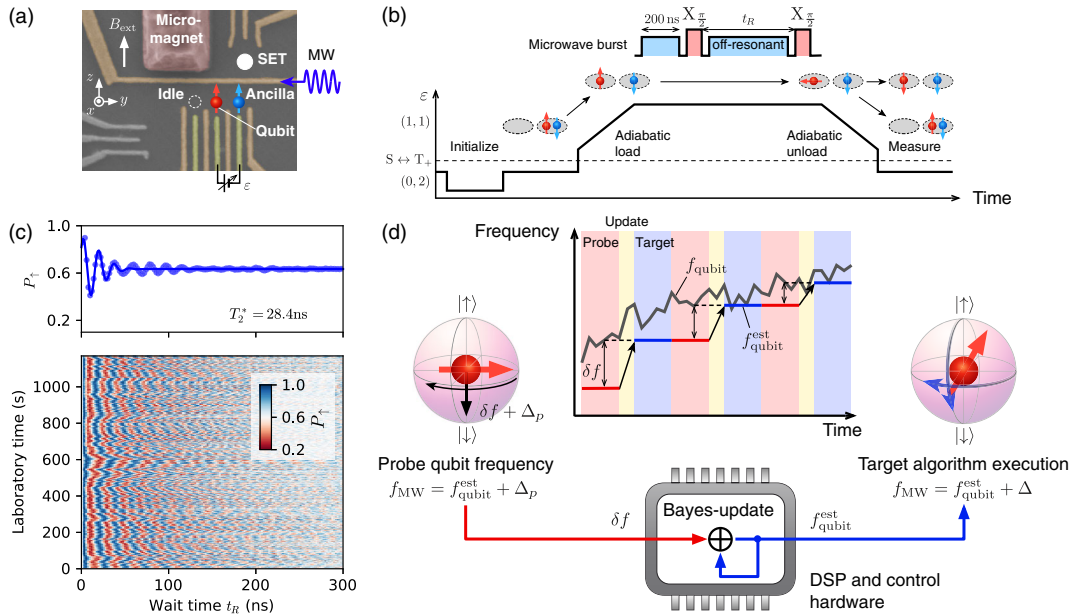

FIG. 2. Ramsey measurement and feedback-control scheme of an electron spin qubit. (a) False-colored scanning electron micrograph image of the TQD device. An electron spin qubit in the middle QD (red arrow with a circle) is controlled by the EDSR where the spin is coupled to a microwave (MW) electric field via a stray magnetic field of the micromagnet deposited on the wafer surface [19]. The right QD hosts an electron spin (blue arrow with a circle) used as a readout ancilla, while the left QD hosts another electron which is unused and decoupled from the two spins. The energy detuning between the middle and the right QDs (ϵ) is gate tunable, and the QD electron occupancies are probed by a proximal single-electron transistor [23]. (b) Schematic of the Ramsey measurement. Two electrons (qubit and ancilla) are initialized to a doubly occupied singlet state in the right QD, and an up-spin qubit is prepared by adiabatically loading one of the electrons to the middle QD [22]. Two $\pi/2$ microwave bursts, separated by time t_R , are applied (before and between these bursts, off-resonant microwave bursts are optionally applied). The ancilla-spin state is not affected by the microwave bursts. The final state is read out by unloading an up-spin (antiparallel to the ancilla) state from the middle QD, while a down-spin (parallel to the ancilla) state remains blocked. (c) Up-spin probability P_\uparrow as a function of t_R . The lower panel shows the Ramsey oscillations whose frequency varies with the laboratory time due to Overhauser field fluctuations. Each data point of P_\uparrow is calculated from 100 single-shot readout outcomes. The upper panel shows the trace obtained by averaging all the oscillations in the lower panel. The decay envelope gives the dephasing time of $T_2^* = 28.4$ ns, a value typical for electron spins in GaAs heterostructures. (d) Schematic of the feedback-control loop for a spin qubit. Data of a Ramsey oscillation as shown in (c) are processed in a digital signal processing (DSP) hardware with programmable logic (FPGA) to estimate the frequency detuning $\delta f = f_{\text{qubit}} - f_{\text{qubit}}^{\text{est}}$ between the current qubit frequency f_{qubit} and its previous estimate $f_{\text{qubit}}^{\text{est}}$ (“probe” step). The value of $f_{\text{qubit}}^{\text{est}}$ is updated to $f_{\text{qubit}}^{\text{est}} \mapsto f_{\text{qubit}}^{\text{est}} + \delta f$ (“update” step), after which the target experiment follows (“target” step). In the ideal case, the subsequent qubit algorithms can be executed with a microwave frequency $f_{\text{MW}} = f_{\text{qubit}}$ exactly (by choosing $\Delta = 0$).

measurements with feedback off ($f_{\text{MW}} = 5.55$ GHz) and feedback on (f_{MW} adjusted to $f_{\text{qubit}}^{\text{est}}$), respectively. The fluctuation of δf is significantly suppressed by the feedback, exhibiting a Gaussian distribution with a variance $\sigma^2 = (0.294 \text{ MHz})^2$ as shown in the inset. As a result, the Ramsey oscillation is substantially prolonged, as shown in Fig. 3(b). Averaging the data with the overall acquisition time of 1200 s gives a decay envelope well in line with the dephasing time expected from σ , $T_2^* = 1/(\pi\sqrt{2}\sigma) = 766.7$ ns.

The gain of T_2^* is therefore directly associated with the achievable value of σ , which, in turn, is limited by the resolution of the Bayesian estimation. To demonstrate this association, we plot σ^2 in Fig. 3(c) as a function of the feedback latency Δt , defined as the time interval between the probe and target steps plus the average time spent in

each step (see Appendix A). For large latency, σ^2 approaches the variance of the qubit frequency correlator in the laboratory frame, $\sigma_B^2(\Delta t) \equiv \langle [f_{\text{qubit}}(t + \Delta t) - f_{\text{qubit}}(t)]^2 \rangle$. It implies that in this regime σ^2 is dominated [27] by the Overhauser field fluctuations during Δt . For small latency, σ^2 converges to $(0.288 \text{ MHz})^2$. This value is comparable to the bin width of the frequency discretization (0.25 MHz) used in the Bayesian estimation algorithm performed by the feedback hardware. We believe that the variance σ^2 could be further decreased by using a smaller bin width as σ_B^2 continues to decrease with Δt within the measured range, although we are not able to do so due to hardware limitations. The value of σ^2 , and thereby that of T_2^* , can be controlled by Δt , allowing for studying the effects of noise in different frequency ranges.

FIG. 3. Suppressed dephasing of an electron spin qubit in a feedback-controlled rotating frame. (a) Time dependence of the frequency detuning $\delta f = f_{\text{qubit}} - f_{\text{qubit}}^{\text{est}}$ extracted from Ramsey measurements. The blue trace is taken with a fixed f_{MW} , and the red trace is taken with a feedback-controlled f_{MW} . The inset shows the histograms of δf in the two cases. The histogram with the feedback control exhibits a normal distribution with a variance $\sigma^2 = \langle (\delta f)^2 \rangle = (0.294 \text{ MHz})^2$ (black dashed curve). (b) Ramsey oscillations as in Fig. 2(c) but obtained with the feedback control ($\Delta = 50 \text{ MHz}$). The envelope of the oscillation in the upper panel is a Gaussian decay function drawn using dephasing time $T_2^* = 1/(\pi\sqrt{2}\sigma) = 766.7 \text{ ns}$. (c) Variance of δf , $\sigma^2 = \langle (\delta f)^2 \rangle$, as a function of the latency Δt between the probe and target steps (orange circles) and that of the frequency correlator σ_B^2 in the laboratory frame (blue circles) as a function of the time difference Δt . A blue line is a fit to $\sigma_B^2 = D\Delta t^\alpha$ and shows subdiffusive behavior with the exponent $\alpha = 0.84$ similar to a value found for singlet-triplet oscillations [27]. The orange curve is a fit to $\sigma^2 = D\Delta t^\alpha + (0.288 \text{ MHz})^2$.

IV. IMPROVEMENTS OF THE QUBIT CONTROL

We now turn to benchmarking of the qubit-control fidelity with the boosted dephasing time. Figure 4(a) shows Rabi oscillations of the single-spin qubit measured with a varied frequency offset Δ . We observe a clear chevron pattern with the symmetry axis offset from $\Delta = 0$. This

result implies that the qubit frequency f_{qubit} is shifted by a finite ac electric field E of the driving microwave burst, while the frequency probed in a Ramsey measurement corresponds to that of $E = 0$. The magnitude of this shift $[\Delta f_{\text{qubit}}(E, t) = f_{\text{qubit}}(E, t) - f_{\text{qubit}}(0, t)]$ increases quadratically with E , as shown in Fig. 4(b). Similar frequency shifts are observed in silicon devices with micromagnets, attributed to a spatial displacement of the electron wave function [28,29]. This effect is detrimental to our feedback protocol, because $\Delta f_{\text{qubit}}(E, t)$ may vary with time t due to the spatial dependence of the Overhauser field. In order to obtain $f_{\text{qubit}}^{\text{est}} = f_{\text{qubit}}(E, t)$ directly in the probe step, we apply an off-resonant microwave burst at $f_{\text{off}} = 5.4 \text{ GHz}$ [$f_{\text{qubit}} - f_{\text{off}} > 200 \text{ MHz}$] during the interval of t_R which induces nominally the same displacement and the same $\Delta f_{\text{qubit}}(E, t)$ as for the target step. In addition, a 200-ns-long off-resonant preburst is applied to stabilize a transient component of the microwave-induced frequency shift [29]. The frequency is switched between f_{off} and f_{MW} within 1 ns using a high-speed microwave switch (see Supplemental Material [30]). We use this modified Ramsey sequence in the probe step and focus on the target step performed at zero detuning [$\Delta = 0$, $f_{\text{qubit}}^{\text{est}} = f_{\text{qubit}}(E, t)$] in all measurements described below.

Figure 4(c) shows a typical Rabi oscillation at zero detuning. It shows a nearly exponential decay, which is common for silicon QDs [6,31] but atypical for GaAs [21,32]. We extract the Rabi frequency f_{rabi} and the decay time of the driven oscillation T_2^{rabi} from fitting and plot their dependence on the driving field amplitude in Fig. 4(d). For a given field amplitude, we find that both f_{rabi} and T_2^{rabi} are influenced by interdot detuning energy that modulates spin-electric-coupling (SEC) strength (see Appendix C). We therefore optimize the detuning energy for the highest quality factor, defined as the number of typical qubit operations available within the Rabi decay time. We reach a quality factor of $Q = 2f_{\text{rabi}}T_2^{\text{rabi}} = 85 \pm 8$ [see Fig. 6(b) in Appendix C], comparable to natural silicon QDs [17,31]. The value predicts the fidelity of a π gate of $e^{-1/Q} = 98.8 \pm 0.1\%$. We test this prediction using randomized benchmarking [33] and find an X_π gate fidelity of $99.04 \pm 0.23\%$ [see Fig. 4(e)], close to the Q -factor limited value. This fidelity is the highest for single-spin qubits in GaAs reported so far. We notice, however, that the average single-gate fidelity is $97.50 \pm 0.05\%$, most likely limited by systematic errors in the other gates (unitary errors) due to the microwave setup in the present study (see Supplemental Material [30]). This issue would be readily resolved by integrating an established technique of quadrature amplitude modulation [18,31] with the FPGA in the microwave generation setup. The X_π gate is least affected by microwave imperfections, as we calibrate the control pulse line primarily for this gate.

FIG. 4. Coherent control and benchmarking of a single-electron spin with the feedback. (a) Typical Rabi oscillations versus the offset Δ obtained in the feedback-controlled rotating frame. A horizontal white dashed line indicates the microwave-induced shift of the qubit frequency, Δf_{qubit} . (b) Microwave-amplitude dependence of the qubit frequency shift. A blue line is a fit to the data showing that the amplitude dependence is quadratic ($\propto E^{1.95 \pm 0.18}$). (c) Rabi oscillations obtained at zero detuning upon compensating for the induced shift Δf_{qubit} . Namely, an off-resonant microwave burst with the same amplitude as the one used for the Rabi measurement is applied before and during the Ramsey measurement [see Fig. 2(b)]. A similar off-resonant burst is also applied for 200 ns before the Rabi drive of duration t_b to stabilize the value of the frequency shift. (d) Microwave-amplitude dependence of the Rabi frequency (blue circles) and the Rabi decay time (red squares with lines). A blue line is a linear fit to the low-amplitude data of the Rabi frequency. (e) Normalized sequence fidelities for standard (top) and interleaved (others) randomized benchmarking. Traces are offset by 0.4 for clarity. The standard sequence shows an exponential decay with an average single-gate fidelity of $97.50 \pm 0.05\%$. Interleaved sequences are annotated with corresponding single-qubit gates and extracted fidelities.

V. DISCUSSION: LIMITS ON THE SPIN-QUBIT CONTROL FIDELITY

What is the physical mechanism limiting the Rabi decay time and the ultimate control fidelity of a single-spin qubit in this system? One obvious candidate is the residual inhomogeneity of f_{qubit} or, in other words, the quasistatic noise δf . However, this contribution should lead to a power-law envelope [34,35] of the Rabi decay $[1 + (2\pi\sigma^2 t/f_{\text{rabi}})^2]^{-1/4}$, as opposed to the exponential one seen in Fig. 4(c). For $f_{\text{rabi}} \gg \sigma$, the initial decay could be approximated by a Gaussian envelope with [21] $T_2^{\text{rabi}'} = f_{\text{rabi}}/(\pi\sigma^2)$, leading to $T_2^{\text{rabi}'} = 74 \mu\text{s}$ with $f_{\text{rabi}} = 20 \text{ MHz}$. This value is an order of magnitude larger than the measured decay time. Also, assuming that unitary errors are removed [18], the qubit control fidelity as high as $\exp[-(2f_{\text{rabi}}T_2^{\text{rabi}'})^{-2}] > 99.9999\%$ could be reached.

We conclude that such quasistatic noise is, therefore, not the main limiting factor of the ultimate qubit control fidelity.

We consider three other noise sources as possibly relevant to the Rabi decay [14,36]: the quasistatic noise in f_{rabi} , the transverse noise at the electron Larmor frequency leading to spin relaxation, and the longitudinal noise in f_{qubit} at the Rabi frequency. The quasistatic noise in f_{rabi} could be caused by fluctuations of the microwave driving amplitude or SEC. However, this mechanism would also lead to a Gaussian decay envelope with $T_2^{\text{rabi}} \propto f_{\text{rabi}}^{-1}$, inconsistent with Fig. 4(c). The spin relaxation is also unlikely, at least in the range of $f_{\text{rabi}} < 20 \text{ MHz}$, because it cannot explain the increase of T_2^{rabi} with f_{rabi} . Therefore, we conclude that T_2^{rabi} is most likely dominated by the high-frequency (on the order of f_{rabi}) longitudinal noise in f_{qubit} , which inherently leads to an exponential Rabi decay.

FIG. 5. Rabi noise spectroscopy. (a) Power spectral density $S(f)$ of the longitudinal noise in f_{qubit} (red circles) extracted from the data in Fig. 4(d). Vertical gray lines show Larmor precession frequencies for three nuclear species (^{75}As , ^{69}Ga , and ^{71}Ga) calculated with the micromagnet-induced field component of $B_z^{\text{MM}} = 70$ mT. Black and green lines are guides to the eye for f^{-1} and f^2 dependence, respectively. The inset illustrates electron-nuclear spin coupling in an inhomogeneous magnetic field. Each nuclear spin is randomly oriented and precesses around a local magnetic field vector $\mathbf{B}(\mathbf{r}_k)$, leading to an oscillatory Overhauser field in the z direction. (b) Comparison of $S(f)$ in (a) and those extracted from Ramsey measurements. The power spectral density of δf in Ramsey measurements is calculated by the fast Fourier transform of $\delta f(t)$. The spectral density taken with small SEC and feedback off (blue) shows the $f^{-1.7}$ dependence (black dashed line) similar to those observed for nuclear spin diffusion noise [15,16]. The spectral density is significantly suppressed with feedback on (orange) down to a level determined by the precision of the feedback control. The flat noise spectrum suggests that the residual low-frequency noise is uncorrelated. A peak at 2 Hz is due to the vibration of the dilution refrigerator. The power spectral density increases as the SEC is increased (red curve in the top left), and it follows the f^{-1} dependence (black solid line) in line with $S(f)$ extracted from the Rabi spectroscopy in (a) (red curve in the bottom right).

When the high-frequency noise in f_{qubit} dominates, one can relate [14,36] the noise power spectral density $S(f)$ at the Rabi frequency to the exponential-decay rate of the Rabi oscillations [see Appendix C]. The power spectral density $S(f)$ extracted in this way is plotted in Fig. 5(a). For $f > 20$ MHz, it grows rapidly with f . It could be due to thermal noise caused by microwave-induced heating [29], with the consistent scaling $P \propto E^2 \propto f_{\text{rabi}}^2$. On the other hand, we cannot exclude a Rabi decay through spin relaxation in this range, possibly caused by, for example, electron exchange with reservoirs due to photon-assisted tunneling [37,38]. Since we cannot extract more information of the intrinsic noise density, we do not discuss this range further.

We turn to the other frequency range, $f < 20$ MHz. Here, $S(f)$ shows three prominent peaks at nuclear Larmor precession frequencies of ^{75}As , ^{69}Ga , and ^{71}Ga . It clearly suggests that such high-frequency noise sources indeed influence the Rabi decay of the spin qubit. The hyperfine coupling between a single-electron spin $\hat{\mathbf{S}}$ and nuclear spins $\hat{\mathbf{I}}_k$ is given by $H_{\text{hf}} = \sum_k A_k \hat{\mathbf{S}} \cdot \hat{\mathbf{I}}_k$, where A_k is a coupling constant dependent on each nuclear site \mathbf{r}_k indexed by k . This coupling results in an Overhauser field component parallel to the external field, $B_z^{\text{nuc}} \propto \sum_k A_k \hat{I}_k^z$. When nuclear spins precess around the z axis, B_z^{nuc} is constant and there is no noise at the Larmor frequencies. In the present device, however, the stray magnetic field from the

micromagnet induces field inhomogeneity, making each nuclear spin at \mathbf{r}_k precess around a local magnetic field vector $\mathbf{B}(\mathbf{r}_k)$ slightly off the z axis [see the inset in Fig. 5(a)]. The inhomogeneity of the nuclear spin polarization leads to small but finite residual oscillations of B_z^{nuc} at the nuclear precession frequencies.

Apart from the three spectral peaks, we find that $S(f)$ follows f^{-1} dependence at $f < 20$ MHz. It suggests that the f^{-1} noise background in the range of tens of megahertz is the dominant limiting factor of the qubit control fidelity. The $f^{-\beta}$ dependence with $\beta = 1$ differs from $\beta \sim 1.7$ for the nuclear spin diffusion noise [15,16] at low frequencies [see Fig. 5(b)] extracted from the data in Figs. 2 and 3 (small-SEC regime). In addition, we confirm that the amplitude of $S(f)$ is larger for a larger SEC (see Fig. 7 in Appendix C). We therefore conclude that the f^{-1} spectrum arises from charge noise and SEC provided by the micromagnet stray field [6]. Indeed, from a Ramsey measurement performed in the condition optimized for the large quality factor (large-SEC regime), we extract the low-frequency ($f < 100$ Hz) noise in line with the f^{-1} dependence [Fig. 5(b)]. A similar f^{-1} noise spectrum over seven decades of frequency has been observed in an isotopically purified ^{28}Si device [6]. Approximating $S(f) = A^2/f$, however, we find $A \sim 0.6$ MHz being 2 orders of magnitude larger than $A \sim 1.6$ kHz found in

the ^{28}Si device. It is also an order of magnitude larger than $A \sim 0.1$ MHz observed in a GaAs device without a micro-magnet [16]. The difference can be partly attributed to large SEC in the present device, as $S(f)$ is reduced by 2 orders of magnitude by decreasing SEC [see Fig. 5(b)], at least at low frequencies. SEC also depends on the orbital energy splitting determined by the confinement potential and effective mass. However, the influence of other factors on A , such as material properties and experimental setups, requires further investigations.

In summary, we demonstrate 24-fold enhancement of the dephasing time T_2^* of a GaAs single-electron spin qubit. The enhancement relies on suppressing the nuclear spin noise by feedback and is limited by classical control electronics that can be improved further. The feedback also boosts the qubit overall performance: We reach the quality factor of $Q = 85 \pm 8$ and the π -gate fidelity of $99.04 \pm 0.23\%$. We find that, despite our device being a GaAs quantum dot, the ultimate fidelity with the feedback is not limited by nuclear-spin noise. The culprit is the $1/f$ charge noise leaking into the qubit through the micro-magnet field gradient at megahertz frequencies.

APPENDIX A: ADDITIONAL DETAILS OF THE FEEDBACK PROTOCOL

Our feedback-control protocol is implemented on a Xilinx ZedBoard device equipped with a coupled central

processing unit and programmable logic. The device is interfaced with an AD-FMCOMMS2-EBZ peripheral board from Analog Devices which provides integrated rf demodulators, 12-bit digital-to-analog converters (DACs) with a sampling rate up to 122.88 million samples per second, and local oscillators (LOs) operating at up to 6 GHz. The demodulators and DACs are used to digitize the rf charge-sensing signal for single-shot spin readouts, and one of the LOs generates the driving microwave at f_{MW} for the EDSR. This system enables rapid switching of f_{MW} conditioned on the spin measurement outcomes without overhead for the data transfer between different equipments. The off-resonant microwave burst is generated from a discrete signal generator and fed to the same signal path via a microwave switch. The whole setup is described in Supplemental Material [30].

For the realtime feedback control, we first take 150 single-shot data points of a Ramsey oscillation with varied intervals $t_R = 2, 4, \dots, 300$ ns in the probe step. Each measurement sequence shown in Fig. 2(b) takes $T_R = 31.71 \mu\text{s}$, giving $T_p = 150T_R \approx 4.8$ ms for one probe step. We update the value of $f_{\text{qubit}}^{\text{est}}$ based on δf obtained from the Bayesian estimation [10,27] and adjust the microwave frequency to $f_{\text{MW}} = f_{\text{qubit}}^{\text{est}} + \Delta$ for the target experiment. We wait for T_w before starting the target step, and we find that T_w needs to be longer than 2 ms to stabilize the microwave output. The time T_t spent in the target step depends on the type of the experiment, and it is $T_t = T_p$ in the case of the measurement shown in Fig. 3. Thus, we define the feedback latency between the probe and target steps as $\Delta t = T_p/2 + T_w + T_t/2$, which can be controlled by changing T_w .

APPENDIX B: DECOHERENCE OF SPIN QUBITS

Here, we summarize our model of spin (qubit) decoherence in free and driven evolutions using the formulation in Ref. [12], which is independent of the microscopic origin of the noise.

1. Decay in free evolution

The spin coherence during free evolution is characterized by the decay envelope of Ramsey oscillations, also called a free induction decay. The dynamics of a spin is described by two processes: the longitudinal relaxation (depolarization) and the pure dephasing. The longitudinal relaxation leads to an exponential decay with the rate $\Gamma_1 = T_1^{-1}$. Fermi's golden rule gives $\Gamma_1 = \pi^2 S_T(f_{\text{qubit}})$, where $S_T(f_{\text{qubit}})$ is the power spectral density (PSD) of the transverse noise at the qubit resonance frequency f_{qubit} . On the other hand, the pure dephasing is caused by the longitudinal noise (fluctuation of the qubit frequency δf), with the PSD given by $S_L(f) = \int_{-\infty}^{\infty} \langle \delta f(t) \delta f(t + \tau) \rangle \exp(-i2\pi f \tau) d\tau$. If the noise is short correlated (white

noise), it leads to an exponential decay with the rate $\Gamma_\varphi = 2\pi^2 S_L(0)$. In this case, the transverse relaxation (dephasing) of the free evolution is given by an exponential envelope with the rate $\Gamma_2 = T_2^{-1} = \frac{1}{2}\Gamma_1 + \Gamma_\varphi$.

The pure dephasing of a spin qubit is often dominated by a longer correlated noise, with its spectral density increasing at lower frequencies. The decay envelope is then generally nonexponential, which we here express as the decoherence function $W(t)$. For Gaussian noise, $W(t)$ is expressed as

$$W(t) = \exp\left(-\frac{t^2}{2}(2\pi)^2 \int_{-\infty}^{\infty} df S_L(f) \text{sinc}^2(\pi ft)\right), \quad (\text{B1})$$

with $\text{sinc}x = \sin x/x$. We divide $W(t)$ into two parts, $W(t) = W^{\text{static}}(t)W^{\text{high}}(t)$, where W^{static} describes the contribution from the quasistatic noise ($|f| < 1/t$) and W^{high} describes the higher-frequency contribution ($|f| > 1/t$). Combined with the longitudinal relaxation, the decay envelope of the free evolution is given by

$$E^{\text{free}}(t) = W^{\text{static}}(t)W^{\text{high}}(t) \exp(-\Gamma_1 t/2). \quad (\text{B2})$$

In the pure dephasing of the free evolution, the effect of W^{high} can be neglected [$W^{\text{high}}(t) = 1$]. The quasistatic part is evaluated using $\text{sinc}(\pi ft) \sim 1$ for $|f| \ll 1/t$ as

$$W^{\text{static}}(t) \approx \exp\left(-\frac{t^2}{2}(2\pi\sigma)^2\right), \quad (\text{B3})$$

where $\sigma^2 = \lim_{T \rightarrow \infty} (1/T) \int_0^T |\delta f(t)|^2 dt = \int_{-\infty}^{\infty} S_L(f) df$ is the variance of the qubit frequency detuning δf . This part corresponds to the Gaussian decay with $T_2^* = 1/(\pi\sqrt{2}\sigma)$ usually obtained in the quasistatic approximation, where δf is considered constant during each qubit evolution but Gaussian distributed in an experimental run. This approximation is valid in our case, where σ and T_2^* are dominated by the quasistatic noise due to the Overhauser field fluctuation with $S_L(f) \propto f^{-\beta}$ and $\beta \sim 2$. The feedback control with the latency Δt described in the main text sets a low-frequency cutoff of $S_L(f)$ at $f_c \sim 1/\Delta t$, thereby reducing σ^2 and enhancing T_2^* . On the other hand, the feedback would be less effective for $\beta \leq 1$, where noise at higher frequencies contributes more to T_2^* .

2. Decay in driven evolution

Now, we turn to the spin coherence during driven evolution, considering a measurement of Rabi oscillations. The spin dynamics is described in the frame rotating with the driving frequency f_{MW} . The spin rotates around the vector sum of the driving field f_{rabi} along the x axis and the microwave frequency detuning $\Delta_q = f_{\text{MW}} - f_{\text{qubit}}$ along the z axis. The total field is tilted by an angle $\eta = \arctan(f_{\text{rabi}}/\Delta_q)$ from the z axis, and its length is

$f_R = \sqrt{f_{\text{rabi}}^2 + \Delta_q^2}$. Decoherence in driven evolution is considered by separating the quasistatic ($|f| < 1/t$) part and the higher-frequency ($|f| > 1/t$) part of the noise. The Rabi decay envelope is given by

$$E^{\text{rabi}}(t) = W_{\text{rabi}}^{\text{static}}(t)W_{\text{rabi}}^{\text{high}}(t) \exp(-\tilde{\Gamma}_2 t), \quad (\text{B4})$$

with $\tilde{\Gamma}_2$ the transverse relaxation rate in the rotating frame.

The contribution of the higher-frequency noise is calculated by mapping $S_L(f)$ and $S_T(f)$ to the components transverse and longitudinal with respect to the total field in the rotating frame. Assuming η is constant ($\Delta_q = \Delta$ and $f_{\text{qubit}} = f_{\text{qubit}}^{\text{est}}$), the longitudinal relaxation rate in the rotating frame is

$$\tilde{\Gamma}_1 = \sin^2 \eta \Gamma_\nu + \frac{1 + \cos^2 \eta}{2} \Gamma_1, \quad (\text{B5})$$

with $\Gamma_\nu = 2\pi^2 S_L(f_R)$. Similarly, $S_T(f_{\text{qubit}})$ contributes to the pure dephasing via $\tilde{\Gamma}_\varphi = \frac{1}{2}\Gamma_1 \sin^2 \eta$, leading to the transverse relaxation rate

$$\tilde{\Gamma}_2 = \frac{1}{2}\tilde{\Gamma}_1 + \tilde{\Gamma}_\varphi = \frac{3 - \cos^2 \eta}{4} \Gamma_1 + \frac{1}{2} \Gamma_\nu \sin^2 \eta. \quad (\text{B6})$$

The longitudinal noise $S_L(f)$ also contributes to $W_{\text{rabi}}^{\text{high}}(t)$, which is obtained by replacing $S_L(f)$ in Eq. (B1) with $S_L(f) \cos^2 \eta$ and setting a low-frequency cutoff to $1/t$.

The contribution of the quasistatic noise is calculated by averaging the Rabi oscillations with the Gaussian-distributed noise of Δ_q around Δ , $\Delta_q - \Delta = f_{\text{qubit}}^{\text{est}} - f_{\text{qubit}} = -\delta f$. At zero detuning $\Delta = 0$, this calculation gives a power-law decay [35]

$$W_{\text{rabi}}^{\text{static}}(t) = \left[1 + \left(2\pi \frac{\sigma^2 t}{f_{\text{rabi}}}\right)^2\right]^{-1/4}. \quad (\text{B7})$$

In addition, this averaging leads to an initial phase shift [34] in the Rabi oscillation, which, however, is negligibly small for $f_{\text{rabi}} \gg \sigma^2 t$ relevant here. Since $W_{\text{rabi}}^{\text{high}}(t) = 1$ for $\Delta = 0$ and $|\delta f| \ll f_{\text{rabi}}$, the decay envelope at zero detuning is simplified to

$$E_0^{\text{rabi}}(t) = W_{\text{rabi}}^{\text{static}}(t) \exp\left[-\left(\frac{3}{4}\Gamma_1 + \frac{1}{2}\Gamma_\nu\right)t\right]. \quad (\text{B8})$$

For $S_L(f_{\text{rabi}}) \gg S_T(f_{\text{qubit}})$, it is $\Gamma_\nu \propto S_L(f_{\text{rabi}})$ that dominates the exponential part.

APPENDIX C: EXTRACTION OF THE NOISE POWER DENSITY $S(f)$

To increase the qubit control fidelity by increasing f_{rabi} , a larger SEC is favorable. In the present device, we can tune

FIG. 6. Coherent oscillations with a large SEC. These data are taken in a gate-bias condition similar to those of Figs. 4 and 5, where the SEC is increased. (a) Ramsey oscillation. Spin-up probability P_{\uparrow} is measured as a function of t_R with the feedback on ($\Delta = 30$ MHz). The solid curve is a fit to the Gaussian-decaying oscillation with $T_2^* = 103.7$ ns. (b) Rabi oscillation for $Q = 85$. The solid curve is a fit to the exponentially decaying oscillation with $f_{\text{rabi}} = 33.64 \pm 0.01$ MHz and $T_2^{\text{rabi}} = 1.26 \pm 0.12$ μ s.

the SEC by gate-controlled interdot energy detuning which could change either the electron confinement or the local slanting magnetic field [20]. However, a larger SEC also enhances the susceptibility of the spin qubit to charge noise, leading to a larger PSD of the qubit frequency noise. After increasing the SEC for Figs. 4 and 5, we notice that the dephasing time is indeed reduced to $T_2^* \sim 100$ ns as shown in Fig. 6(a). This result suggests that the dephasing time observed in free evolution (a Ramsey experiment) is dominated by charge noise in this regime.

To extract $S_L(f)$ in Fig. 5 by fitting the Rabi decay envelopes with Eq. (B8), we calculate σ^2 from the Ramsey decay envelope. If $S_L(f) = A^2/f$ holds in the whole frequency range of interest, $f_c < |f| < 1/t$, and Γ_1 is neglected, the decay envelope in Eq. (B2) reduces to

$$E^{\text{free}}(t) \approx W^{\text{static}}(t) = \exp\left[-t^2(2\pi A)^2 \ln \frac{1}{f_c t}\right] \quad (\text{C1})$$

with $1/T_2^* = 2\pi A \sqrt{\ln(1/f_c t)}$. Using $T_2^* = 103.7$ ns, $f_c = 0.5$ kHz, and $t = 100$ ns, we obtain $A = 0.5$ MHz.

FIG. 7. Microwave amplitude dependence of the Rabi frequency (a) and Rabi noise spectroscopy (b) with different SECs. Red circles are taken in the “large SEC” condition with $A = 0.6$ MHz as shown in Fig. 5. Blue squares are taken in a condition where the SEC is increased to $A = 1.0$ MHz and the Q factor is slightly lower.

In the Rabi decay, on the other hand, the high-frequency cutoff is determined by $t \sim T_2^{\text{rabi}} \sim 2$ μ s. The variance relevant to $W_{\text{rabi}}^{\text{static}}$ is therefore estimated to be $\sigma^2 = 2A^2 \ln(1/f_c t) = 3.3$ MHz².

The expression of T_2^* in the above also explains why the dephasing time shown in Fig. 6(a) remains so short with the feedback control. The T_2^* value is improved only logarithmically by increasing the low-frequency cutoff f_c . Nevertheless, the feedback control is essential to suppress quasistatic noise especially during driven evolution. As shown by Eq. (B8), significant portion of $S_L(f)$ in $W_{\text{rabi}}^{\text{high}}(t)$ is decoupled from the Rabi decay by maintaining $\Delta = 0$ using the feedback control, so that one can reach the Γ_ν -limited regime.

To examine the validity of the analysis, we analyze another set of data taken at an even larger SEC. Figure 7 shows the comparison of the extracted PSD and the one plotted in Fig. 5(a). Because of the increased (transverse) SEC, the Rabi frequency is 1.9 times larger at the same driving microwave field. The high-frequency noise PSD is also increased as shown in Fig. 7(b). The value of A is found to increase by a factor of 1.7 in agreement with the increase of the longitudinal SEC. This consistency confirms that the main source of the Rabi decay is the high-frequency charge noise coupled to the spin qubit.
