ABSTRACT

Objective: Assess achievement of low-density lipoprotein cholesterol (LDL-C) targets in European Society of Cardiology (ESC)/European Atherosclerosis Society (EAS) guidelines.

assessed study quality using the Risk of Bias for Non-Randomised Studies–Interventions (ROBINS-I) tool. Primary outcome was the proportion of patients achieving LDL-C targets in the 2011/2016 ESC/EAS guidelines. Where available, patient characteristics were presented as means weighted by sample size. The proportions of patients achieving LDL-C targets in the 5 years before and after publication of the 2011 guidelines were compared using a chi-square test.

Results: Across 81 eligible studies (303,534 patients), achievement of LDL-C < 1.8 mmol/L was poor among patients with established CVD (16%; range 9–56%) and at very high risk of CVD (SCORE \geq 10% [18%; 14–25%]). In individuals with FH, SCORE 5–10%, or diabetes and target organ damage, LDL-C < 2.5 mmol/L was achieved by 15% (9–22%), 46% (21–55%) and 13% (6–34%), respectively. Comparing the 5 years before/after publication of the 2011 guidelines, target achievement increased significantly over time but remained suboptimal (LDL-C < 1.8, 22% versus 15%; LDL-C < 2.5, 68% versus 61%; both $p < 0.001$; established CVD group only).

Conclusions: These data show suboptimal LDL-C control among European patients at high risk of CVD. Those at greatest overall risk (clinically established CVD or at least a 10% 10-year risk of fatal CVD) had the lowest achievement of 2011/2016 EAS/ESC LDL-C targets. With lower LDL-C targets advocated in 2019 ESC/EAS guidelines, this unmet need will increase.

Key Summary Points

High levels of low-density lipoprotein cholesterol (LDL-C) are a known risk factor for cardiovascular (CV) events and risk-based LDL-C targets are central to dyslipidaemia treatment guidelines.

This systematic review describes data from 81 observational studies reporting LDL-C levels measured between 2006 and 2017, and attainment of LDL-C targets set out in 2016 EAS/ESC dyslipidaemia guidelines, among European patients at high or very high risk of cardiovascular disease (CVD).

Few patients at high or very high risk of CV events achieved recommended LDL-C target levels. Those at the greatest overall risk, including those with a greater than 10% 10-year risk of fatal CVD (as assessed by SCORE) or clinically established CVD, had the lowest achievement of LDL-C targets.

These findings indicate a significant unmet need in LDL-C control among patients at high/very high risk of CV events and offer an opportunity to attenuate CV events on a population level.

Recent 2019 ESC/EAS dyslipidaemia guidelines recommend LDL-C levels be lowered as much as possible to prevent CVD, and the unmet need in high/very high-risk patients will be even greater when assessed against these new guideline targets.

INTRODUCTION

Cardiovascular disease (CVD) is one of the leading causes of morbidity and mortality across Europe, with high levels of low-density lipoprotein cholesterol (LDL-C) widely recognized as a risk factor for CV events [1]. Trials of statin therapy have shown that the benefits of reducing the risk of CV events are proportional to the magnitude of LDL-C lowering [2, 3]. Moreover, LDL-C targets are central to the guidance from the European Society of Cardiology (ESC)/European Atherosclerosis Society (EAS) on the treatment of dyslipidaemias, which recommends overall risk assessment and sets out therapeutic targets for LDL-C [1, 4–6].

While statin trials have shown that reducing LDL-C levels attenuates CVD events in at-risk individuals, driven largely by a reduction in rates of myocardial infarction (MI), the application of current guidelines on a population level in Europe is poorly understood. In the L-TAP 2 study, conducted across Asia, Europe, Latin America and North America, 9955 patients with dyslipidaemia on stable lipid-lowering therapy were enrolled [7]. Achievement of regional LDL-C targets was 86% in low-risk, 74% in moderate-risk and 67% in high-risk patients, suggesting that the greatest unmet need for LDL lowering was in patients at the highest overall risk for CVD events.

The main objective of this study was to describe the proportion of individuals in Europe, in four selected patient cohorts at high/very high CVD risk, reaching the LDL-C targets recommended in the 2011 and 2016 ESC/EAS guidelines (Table 1). These groups are (1) established CVD, (2) diabetes mellitus (DM)

Table 1 European Society of Cardiology (ESC)/European Atherosclerosis Society (EAS) LDL-C targets for high/very high-risk groups

Clinical risk categories	Target LDL-C levels
Established CVD	LDL-C < 1.8 mmol/L or 50% reduction in LDL-C
DM with target organ damage	LDL-C < 1.8 mmol/L or 50% reduction in LDL-C
FH	LDL-C < 2.5 mmol/L or maximal reduction in LDL-C with any possible drug combination plus LDL apheresis
SCORE \geq 10% considered very high risk, SCORE 5–10% considered high risk	Very high risk, LDL-C < 1.8 mmol/L or 50% reduction in LDL-C; high risk, LDL-C < 2.5 mmol/L

CVD cardiovascular disease, *LDL-C* low-density lipoprotein cholesterol, *DM* diabetes mellitus, *FH* familial hypercholesterolaemia, *SCORE* Systematic COronary Risk Evaluation calculates 10-year risk of fatal cardiovascular disease as a percentage

with target organ damage, (3) familial hypercholesterolaemia (FH) and (4) individuals with at least a 5% 10-year risk of fatal CVD as determined by the Systematic Coronary Risk Evaluation (SCORE) tool [8]. A secondary objective was to evaluate whether the publication of the guidelines in 2011 resulted in an improvement of LDL-C control in these risk groups.

METHODS

This systematic review was conducted according to the protocol registered with PROSPERO (Registration number CRD77844) and in accordance with PRISMA and MOOSE guidelines [9, 10].

Eligibility

The following studies were included: (1) observational studies; (2) reporting LDL-C levels or LDL-C target attainment in European patients measured between 1 August 2006 and 31 August 2016; (3) with at least 200 individuals in one of the high/very high-risk cohorts defined in Table 1 (and as per 2011 ESC/EAS guidelines [5]; the LDL-C targets recommended in the 2016 update of these guidelines did not change substantially [1, 4]); (4) reporting exclusively on individuals aged 18 years or more. All studies not meeting these pre-specified inclusion criteria were excluded. Where studies reported on mixed cohorts or patients outside Europe, studies were included if at least 80% of the overall study population met the cohort definition or were from within Europe, respectively.

Search Strategy

Two reviewers independently searched Medline, EMBASE and Cumulated Index to Nursing and Allied Health Literature (CINAHL) for Medical Subject Heading (MeSH) and keywords related to diabetes mellitus (DM), established CVD, familial hypercholesterolaemia (FH), SCORE and LDL-C (Supplementary Appendix 1). These searches were combined with a search strategy to identify studies reporting observational data

in humans and supplemented by examining reference lists of included studies, reviews and meta-analyses [11, 12]. No language restrictions were applied.

Selection of Studies and Data Extraction

Two reviewers independently screened titles and abstracts to identify articles suitable for full text review, independently reviewed the full text articles, and extracted data on the following variables (where available, and using a pre-defined data extraction form [Supplementary Appendix 2]): study details (design, location, number of patients in EAS/ESC high-risk group reported); patient characteristics (prevalent DM, hypertension, active smoking, BMI, statin therapy, use of any lipid-lowering therapy); and outcomes (mean and range of LDL-C level, achievement of LDL-C targets < 2.5 or < 1.8 mmol/L, myocardial infarction, stroke, major adverse cardiovascular events [MACE], all-cause mortality). Any conflicts during the PRISMA process were to be resolved by the lead author (EB). Where studies reported duplicate data, the most recent report from the same cohort was included to reflect contemporary practice and increase power.

Assessment of Risk of Bias

The two reviewers independently assessed the quality of the included studies using the Risk of Bias for Non-Randomised Studies–Interventions (ROBINS-I) tool [13]. This tool assesses bias across seven domains: (1) bias due to confounding, (2) bias in selection of participants, (3) bias in classification of interventions, (4) bias due to deviations from intended interventions, (5) bias due to missing data, (6) bias in measurement of outcomes and (7) bias in selection of the reported result. Overall risk of bias was defined as low, moderate, serious or critical. Sensitivity analyses excluding studies with serious or critical risk of bias for the primary and secondary endpoint were planned.

Statistical Analyses

The primary outcome measure was the proportion of patients achieving LDL-C targets, as defined in the ESC/EAS 2011 (and 2016) guidelines. The proportion of patients achieving LDL-C targets in the 5-year periods before and after publication of the 2011 ESC/EAS guideline, i.e. 1 August 2006–31 July 2011 and 1 August 2011–31 August 2016, respectively, were compared using a chi-square test. Where available, summary characteristics of participants, including LDL-C levels, are presented as mean values weighted by study size. Where LDL-C levels were reported at multiple time points during the 5-year periods before or after the publication of the 2011 ESC/EAS guideline, the most recent values were extracted to reflect contemporary practice. Secondary outcome measures were myocardial infarction, stroke and all-cause mortality. Where not directly reported for these secondary outcomes, event rates per 1000 person-years were calculated by dividing the absolute number of events by the total person-years of follow-up.

Compliance with Ethics Guidelines

There was no patient or public involvement in this research project. This article is based on previously conducted studies and does not contain any studies with human participants or animals performed by any of the authors.

RESULTS

Search Strategy

Of 17,683 potentially relevant publications, 915 studies were identified for full text review. After 47 duplicates were removed, a further 787 studies did not meet the eligibility criteria and were excluded; a total of 81 studies were included in the final analyses (Fig. 1).

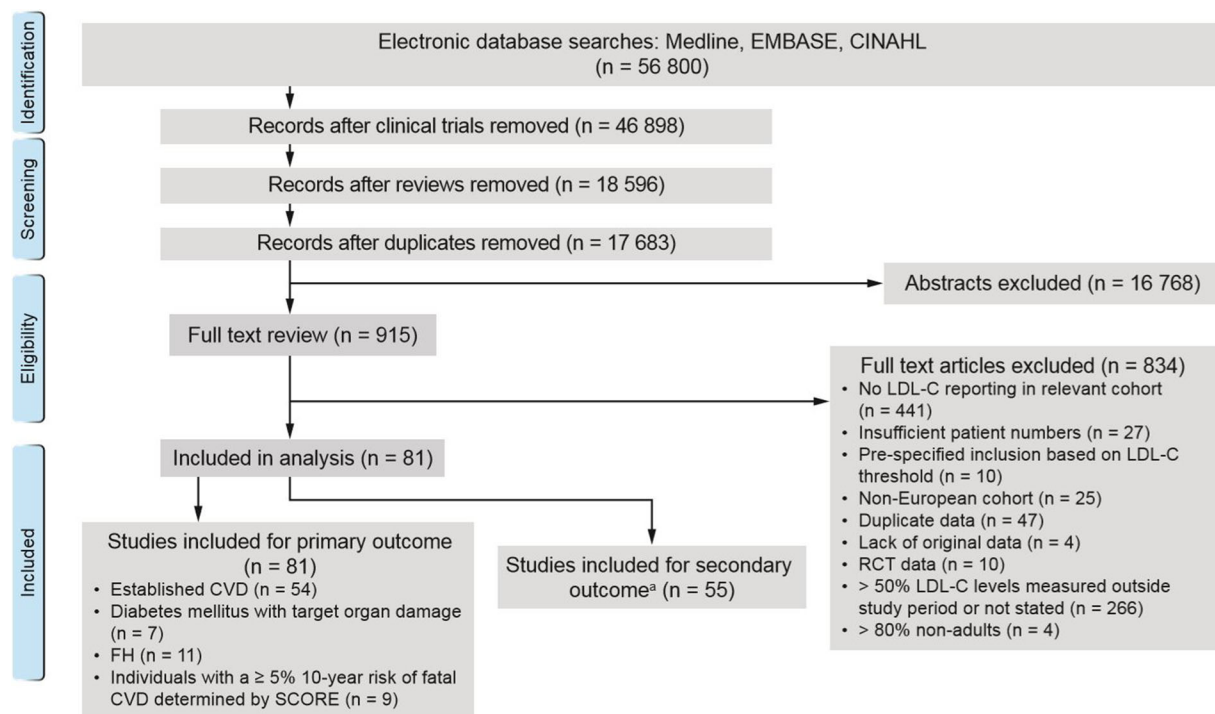

Fig. 1 PRISMA flow diagram. ^aFor the secondary outcome a meaningful comparison was only possible among studies reporting on individuals with established CVD. CINAHL Cumulative Index to Nursing and Allied Health

Overview of Included Studies

Included studies reported on a total of 303,534 patients across the four high/very high-risk groups: *n* = 200,534 patients with established CVD, *n* = 13,339 DM with target organ damage, *n* = 41,594 FH and *n* = 48,067 SCORE ≥ 5%. All studies reported LDL-C levels and/or achievement of LDL-C targets while patients were receiving lipid modification therapy. The majority of included studies were based on registry data or cohort studies (51 studies, 63%); 30 studies (37%) were cross-sectional in design (Supplementary Appendices 2 and 3). Characteristics of included patients are presented in Table 2. The definition of FH used in included studies is presented in Supplementary Appendix 4. Compared with other high/very high-risk groups, those with FH were younger, less likely to be hypertensive or diabetic, and had a lower body mass index. Statin use was frequent among patients with established CVD (89%) and SCORE ≥ 5% (99%); whereas only a minority of patients with FH (35%) or DM with target organ damage (43%) were receiving a statin.

Risk of Bias

The overall risk of bias, measured using the Robins-I tool, was moderate for all included studies; hence, planned sensitivity analyses excluding studies with serious or critical risk of bias were not performed (Supplementary

Appendix 5). No study selected participants on the basis of LDL-C measurements after the study start. Our analyses did not assess the effect size of any intervention on the primary or secondary outcome measures; therefore, no study was considered to have deviated from an intended intervention. Baseline characteristics were reported in the overall population of all studies; however, in six studies our inclusion criteria only applied to one or more subgroups where these characteristics were not reported. No bias in the measurement of outcome was observed in any of the included studies.

Statistical Analysis

Pooled estimates for mean LDL-C levels and the proportion of patients achieving EAS/ESC target LDL-C levels are presented in Table 3. Across the four high/very high-risk groups, mean LDL-C levels were lowest among patients with established CVD (weighted mean 2.8 mmol/L, SD 0.9) and highest among those with FH (weighted mean 4.9 mmol/L, SD 1.9).

The ESC/EAS recommended target LDL-C level of < 1.8 mmol/L for patients with established CVD was achieved in only 16% (range 9–56%) of patients included in this cohort. No study including patients with DM and target organ damage reported on achievement of the EAS/ESC recommended LDL-C target level of < 1.8 mmol/L; however, achievement of the less stringent LDL-C target of < 2.5 was similarly low at 13% (range 6–36%). Among the

Table 3 Mean LDL-C levels and target achievement for high/very high-risk groups

	Established CVD (<i>n</i> = 200,534)	DM + target organ damage (<i>n</i> = 13,339)	FH (<i>n</i> = 41,594)	SCORE ≥ 5% (<i>n</i> = 48,067)

LDL-C low density lipoprotein cholesterol, CVD cardiovascular disease, DM diabetes mellitus, FH familial hypercholesterolaemia, SCORE Systematic COronary Risk Evaluation, NA not available (no study reported these data), – not applicable to this cohort

Fig. 2 LDL-C goal achievement among patients with SCORE 5–10% (high risk) and SCORE \geq 10% (very high risk). Studies included in this figure were those

reporting LDL-C goal achievement stratified by high risk and very high risk [48–51]. LDL-C low-density lipoprotein cholesterol, HR high risk, VHR very high risk

mixed primary and secondary prevention cohort of patients with FH, achievement of the recommended LDL-C target of < 2.5 mmol/L was also low at 15% (range 9–22%). The EAS/ESC guidelines recommend an LDL-C target of < 2.5 mmol/L for patients at high risk, defined by a SCORE of 5–10%, and < 1.8 mmol/L for those at very high risk (SCORE $> 10\%$). Across the four studies reporting LDL-C goal achievement stratified by high/very high risk, goal achievement was greater among patients at high risk (pooled estimate, 46%) compared with very high risk (18%) (Fig. 2).

When comparing the 5-year period before and after the publication of the 2011 ESC/EAS guidelines, a meaningful comparison was only possible among studies reporting on individuals with established CVD. The achievement of LDL-C targets over time for these studies is summarised in Supplementary Appendix 6. Compared with studies reporting LDL-C measurements taken entirely before the publication of the 2011 guidelines, achievement of both LDL-C < 1.8 mmol/L and LDL-C < 2.5 mmol/L was significantly higher in those with measurements made after 2011 (LDL-C < 1.8 mmol/L, 22% versus 15%; LDL-C < 2.5 mmol/L, 68% versus 61%; both $p < 0.001$).

Only 12 studies reported the pre-specified secondary outcomes of MI, stroke or all-cause mortality; 10 of these included participants with established CVD, one study included participants with FH and one included participants with DM (Supplementary Appendix 7). No single study reported all of the pre-specified secondary outcomes. Among individuals with established CVD, event rates for MI (9.3–32.4 per 1000 person-years), stroke (1.2–9.5 per 1000 person-years), MACE (10.7–167.5 per 1000 person-years) and all-cause mortality (3.1–58.5 per 1000 person-years) varied widely between studies.

DISCUSSION

In this systematic review, results from 81 European observational studies suggest poor LDL-C control among patient groups at high/very high risk of cardiovascular events. Achievement of the more aggressive target of < 1.8 mmol/L, as recommended in ESC/EAS 2016 guidelines [1] for individuals at very high risk (established CVD or SCORE $\geq 10\%$), was especially poor, at less than 19% in both risk groups. The proportions of patients reaching the target of < 2.5 mmol/L applicable to the FH and SCORE 5–10% risk groups were also suboptimal

(15% and 46%, respectively). When comparing the 5-year period before and after the publication of the ESC/EAS guideline in 2011 (in the established CVD risk group), rates of LDL-C target achievement improved significantly over time. However, rates of LDL-C target achievement remained suboptimal in the 5-year period after the publication of the 2011 guidelines (LDL-C < 1.8, 22%; LDL-C < 2.5, 68%).

Several multinational surveys have examined the use of lipid-lowering therapy and LDL-C goal attainment in the setting of secondary prevention [14–17]. This systematic review is the first to investigate the achievement of therapeutic targets for LDL-C in observational studies across four clinical risk categories in Europe. In high-dose statin secondary prevention trials conducted in highly selective patient populations, and despite close monitoring of adherence, which is not feasible in clinical practice, a high proportion of patients did not obtain optimal LDL-C levels. The proportion of patients achieving target levels in our study appears to be higher and highlights the discordance between trials and real-world clinical practice. Meta-analyses undertaken by the Cholesterol Treatment Trialists' (CTT) Collaboration on statin trials suggest that a 1.0 mmol/L reduction in LDL-C is associated with a relative risk (RR) of 0.90 (95% CI 0.87–0.93) for all-cause mortality, i.e. a risk reduction of 10%. Major coronary events are similarly reduced by 24% (RR 0.76, 95% CI 0.73–0.79) and stroke by 15% (RR 0.85, 95% CI 0.8–0.89) [2, 3]. Importantly, these benefits were observed irrespective of baseline LDL-C, and at levels below 2 mmol/L, with no evidence to suggest that low LDL-C levels result in any adverse effects to counteract the benefit. In the present study, the mean LDL-C value in the patient group with established CVD was 2.8 mmol/L. Lowering LDL-C among this group to the 1.8 mmol/L target in the 2016 ESC/EAS guidelines would therefore result in meaningful CVD risk reductions on a population level. Our findings suggest that a significant proportion of patients at high or very high risk of CVD are being exposed to LDL-C concentrations far in excess of recommended targets. Future efforts need to address the disparity between evidence-based guidance and clinical

practice and to understand the reasons behind poor LDL-C control among high-risk patients.

Suboptimal LDL-C target achievement was observed despite almost all patients with established CVD and SCORE \geq 5% receiving statins (89% and 99%, respectively). These findings on statin use compare favourably with a US study assessing the impact of the 2013 American College of Cardiology/American Heart Association (ACC/AHA) cholesterol guidelines, where data from the PINNACLE registry showed that 28% of eligible patients with atherosclerotic CVD did not receive any lipid-lowering medication [18]. Underutilisation of lipid-lowering therapy was also reported in an earlier cohort of patients with a history of MI in the US National Health and Nutrition Examination Survey [19]. The poor attainment of LDL-C targets observed in our study suggests that patients at very high risk are not receiving statin therapy at an adequate intensity, as suggested by single country observational studies in the UK and Spain [20, 21]. In addition to specific targets for the risk groups we studied, the 2016 ESC/EAS guidelines advocate an absolute reduction in LDL-C of 50% in very high-risk patients with established CVD, DM with target organ damage, or SCORE \geq 10%. It is therefore possible that insufficient numbers of patients are receiving moderate-intensity or high-intensity statin treatments, defined as regimens which reduce LDL-C by 30–50% and by 50%, respectively. Few data were available on the intensity of statin therapy among participants in the included studies to confirm such a clinical inertia hypothesis; however, inadequate intensity of lipid-lowering therapy in high-risk populations has been widely reported [22, 23]. Registry data from the USA and Europe, for example, suggest that only 23–38% of patients discharged following an MI receive maximal-intensity statin therapy [24–26].

Recent randomised trials have reported additional LDL-C lowering and further reduction in CVD risk with ezetimibe, anacetrapib and two proprotein convertase subtilisin/kexin 9 (PCSK9) monoclonal antibodies, evolocumab and alirocumab [27–32]. While evidence regarding the clinical benefit of these treatments was only available towards the end of the

present study period, any future improvement in LDL-C control is likely to depend, in part, on greater use of non-statin therapy in patients failing to reach target LDL-C or those unable to tolerate statins. Doubling statin doses results in a further 6% reduction in LDL-C with good compliance [33]; however, side effects attributed by patients to therapy increase with dosing intensity [34]. LDL-C thresholds set out in the ESC/EAS 2011 and 2016 guidelines can therefore be used to prompt consideration of non-statin agents to further lower LDL-C and CVD risk [35]. ESC/EAS have published guidance on the use of PCSK9 inhibitors in patients with atherosclerotic CVD and FH, including clinical decision algorithms [36]. An observational report on primary care data in Spain suggests that around 0.3% of the adult population would be candidates for treatment with a PCSK9 inhibitor [37], according to this guidance.

Another possible explanation for low achievement of the 1.8 mmol/L LDL-C target is poor medication adherence. Even in the setting of well-designed controlled studies, discontinuation rates for lipid-lowering therapy are high. The IMProved Reduction of Outcomes: Vytorin Efficacy International Trial (IMPROVE-IT) reported that up to 40% of patients discontinued medication [29]. In large registries of patients with coronary heart disease, statin discontinuation rates are even higher, reaching 50% at 1 year [38–40]. Real-world data on the impact of good adherence (defined as proportion of days covered at least 80%) to lipid-lowering therapy in an Italian cohort at very high CV risk suggests that it is associated with a three times higher probability of reaching the therapeutic LDL-C target [41]. Furthermore, clinical trial and registry data have demonstrated higher mortality rates following statin discontinuation in secondary prevention [42, 43]. Statin discontinuation, in part due to negative press [44, 45], has also been shown to increase the risk of myocardial infarction and cardiovascular mortality [44, 46, 47]. Irrespective of the underlying reasons for the poor achievement of ESC/EAS LDL-C targets reported here, the ESC/EAS guidelines place considerable weight on LDL-C monitoring to measure therapeutic efficacy and patient compliance. Our findings

suggest that this process is not happening effectively in clinical practice across Europe and durable strategies are needed to address gaps in lipid-lowering for primary and secondary prevention in high-risk groups. These findings are particularly relevant following the release of 2019 ESC/EAS dyslipidaemia guidelines, which recommend that LDL-C levels should be lowered as much as possible to prevent CVD [6]. Given our data suggesting that the 2016 LDL-C targets were not being achieved in patients with high/very high-risk CVD, the unmet need in this population will be even greater when assessed against the lower, more aggressive 2019 targets.

As with any systematic review, our limitations reflect those of the included studies. Information on baseline characteristics was incomplete for a large number of studies, especially those where only a subgroup of participants met our inclusion criteria. An additional limitation was our inability to determine the intensity of statin therapy or adherence to prescribed lipid-lowering therapy, both of which may influence LDL-C levels. The low percentage of patients with established CVD and SCORE $\geq 5\%$ achieving target LDL-C levels, despite almost all patients receiving statins (89% and 99%, respectively), suggest that these patients were receiving low- or medium-intensity statins and/or were not adhering to their prescribed lipid-lowering therapy. Data on outcomes of interest were inconsistently reported across the included studies, and individual participant data were lacking, preventing meaningful analyses to examine the influence of LDL-C goal attainment on cardiovascular endpoints. Only a small number of studies involving patients with diabetes and target organ damage were identified, none of which reported achievement of the relevant LDL-C target (< 1.8 mmol/L). Furthermore, only two out of seven studies in patients with diabetes and target organ damage reported achievement of the more conservative target of < 2.5 mmol/L. In future studies, consistent reporting of the relevant LDL-C target achievement in different at-risk populations will allow meaningful updates to the present review and help guide efforts to improve clinical practice.

CONCLUSION

Observational data from across Europe suggest suboptimal LDL-C control across four clinical risk categories for CVD. Those at the greatest overall risk, including those with a greater than 10% 10-year risk of fatal CVD (as assessed by SCORE) or clinically established CVD, had the lowest achievement of LDL-C targets. Attainment of more conservative targets than advocated in current 2019 EAS/ESC guidance was also poor. Our findings suggest a significant unmet need in LDL-C control among individuals at high or very high risk of CVD, and an opportunity to attenuate cardiovascular events on a population level. Given that our data suggest the 2016 LDL-C targets were not being achieved in patients with high/very high-risk CVD, the unmet need in this population will be even greater when assessed against the lower, more aggressive 2019 targets.

Authorship. All named authors meet the International Committee of Medical Journal Editors (ICMJE) criteria for authorship for this article, take responsibility for the integrity of the work as a whole, and have given their approval for this version to be published. All authors contributed to the design of this systematic literature review and the interpretation of the data. All authors provided input to draft

versions of the manuscript, had final control over data interpretation and publication content, and approved the final version.

Disclosures. Eric Bruckert has received consulting fees from AMGEN, Genfit, MSD, Sanofi, Regeneron, Unilever, Aegerion, Chiesi, Rotapharm-MEDA, Lilly, Ionis-pharmaceuticals, AKCEA. Klaus Georg Parhofer has received research grants from MSD and Sanofi; consulting fees from Aegerion, Alexion, Amgen, Berlin-Chemie, Boehringer-Ingelheim, MSD, Regeneron, Sanofi; speakers' fees from Amgen, Berlin-Chemie, MSD, Sanofi. Jose Ramon Gonzalez-Juanatey has nothing to disclose. Børge Nordestgaard has received consulting fees from AstraZeneca, Omthera, Sanofi, Regeneron, Ionis, Aegerion, Dezima, Amgen and Kowa. Marcello Arca has received research grants and consulting fees from Amgen, Regeneron, Sanofi, Akcea, Aegerion; research grants from Chiesi and Pfizer; consulting fees from Alfasigma. Periklis Giovas is an Amgen employee. Kausik Ray has received research grants from Pfizer, Sanofi, Regeneron, Amgen; consulting fees from Amgen, Sanofi, Regeneron, MedCo, Cerenis, Lilly, Ionis Pharma, Abbvie; speakers' fees from Kowa, AstraZeneca, Pfizer, Takeda, Boehringer Ingelheim, Algorithm, Cipla.

Compliance with Ethics Guidelines. This article is based on previously conducted studies and does not contain any studies with human participants or animals performed by any of the authors.

Data Availability. Qualified researchers may request data from Amgen clinical studies. Complete data are available at the following: <https://wwwext.amgen.com/science/clinical-trials/clinical-data-transparency-practices/>.
