Abstract. Small pelagic fish off the coast of Peru in the eastern tropical South Pacific (ETSP) support around 10 % of global fish catches. Their stocks fluctuate interannually due to environmental variability which can be exacerbated by fishing pressure. Because these fish are planktivorous, any change in fish abundance may directly affect the plankton and the biogeochemical system.

To investigate the potential effects of variability in small pelagic fish populations on lower trophic levels, we used a coupled physical–biogeochemical model to build scenarios for the ETSP and compare these against an already-published reference simulation. The scenarios mimic changes in fish predation by either increasing or decreasing mortality of the model's large and small zooplankton compartments.

The results revealed that large zooplankton was the main driver of the response of the community. Its concentration increased under low mortality conditions, and its prey, small zooplankton and large phytoplankton, decreased. The response was opposite, but weaker, in the high mortality scenarios. This asymmetric behaviour can be explained by the different ecological roles of large, omnivorous zooplankton and small zooplankton, which in the model is strictly herbivorous. The response of small zooplankton depended on the antagonistic effects of mortality changes as well as on the grazing pressure by large zooplankton. The results of this study provide a first insight into how the plankton ecosystem might respond if variations in fish populations were modelled explicitly.

1 Introduction

Eastern boundary upwelling systems (EBUSs) are among the most productive regions in the ocean. Despite their small size, they support a large fraction of the world's fisheries (Chavez and Messié, 2009). The northern Humboldt Current System (NHCS) in the eastern tropical South Pacific (ETSP) Ocean is the most productive EBUS, producing 10 % of global fish catches (Chavez et al., 2008) and supporting the fishery of the Peruvian anchovy *Engraulis ringens*, which is the biggest single-species fishery on the planet (Chavez et al., 2003). The ETSP is also characterised by substantial interannual variability (i.e. El Niño–Southern Oscillation; Holbrook et al., 2012) and an intense midwater oxygen minimum zone (OMZ), resulting in high denitrification rates (Farías et al., 2009).

As in other EBUSs, small pelagic fish are highly abundant (Cury et al., 2000) in the NHCS, building up large populations that are severely affected by climate fluctuations. For example, anchovy biomass in the NHCS fluctuated between 10×10^6 and 16×10^6 t in the 1960s (Alheit and Niquen, 2004). Its area of distribution spans from northern Peru to northern Chile and the Talcahuano region off central Chile (Fig. 1 in Alheit and Niquen, 2004). During the El Niño event of 1972, it dropped to 6×10^6 t (Alheit and Niquen, 2004), presumably caused by warming and the resulting decrease in upwelling and production. These unfavourable growth conditions for anchovy might have been exacerbated by fishing pressure (Beddington and May, 1977; Hsieh et al., 2006). From 1992 to 2008, the population of anchovy off the Peru-

vian coast fluctuated between 3×10^6 and 12×10^6 t (Fig. 13 in Oliveros-Ramos et al., 2017).

The Peruvian anchovy is a planktivorous fish whose diet changes over its ontogenic development. Anchovy first-feeding larvae consume mainly phytoplankton, and when they reach a length of 4 mm their diet gradually switches to zooplankton, especially nauplii of copepods (Muck et al., 1989). Adult anchovies' main sources of energy are euphausiids and copepods although phytoplankton is still found in their diet (Espinoza and Bertrand, 2008). The other prominent small planktivorous fish species in the NHCS is the Pacific sardine *Sardinops sagax*, which feeds on smaller particles than anchovy, including phytoplankton and small zooplankton (Ayón et al., 2008a). These two species can therefore be expected to impose a direct top-down control on plankton; at the same time, they may be bottom-up affected by changes in plankton abundance caused by variations in physical forcing.

Pauly et al. (1989) estimated that the total population of anchovy off Peru consumes 12.1 times its own biomass in 1 year. Assuming an area of 6×10^{10} m² (Ryther, 1969) and a conversion factor of zooplankton wet weight to nitrogen of $1000 \text{ mg ww (mmol N)}^{-1}$ (Travers-Trolet et al., 2014a), a fluctuation in anchovy population of 9×10^6 t would result in a change in zooplankton mortality of $5 \text{ mmol N m}^{-2} \text{ d}^{-1}$ from anchovy predation alone, in a top-down-driven ecosystem assuming no non-linearities. The assumption that anchovy can exacerbate a top-down control on zooplankton is supported by a decline in zooplankton concentration in dense aggregations of anchovies (Ayón et al., 2008a, b). On the other hand, co-occurring long-term fluctuations of zooplankton and anchovies at the population scale also indicate a relevant bottom-up control in the NHCS (Alheit and Niquen, 2004; Ayón et al., 2008b).

Numerical models are valuable tools to examine the potential tight coupling across a large range of trophic levels and the mutual interactions among the different components, including top-down and bottom-up effects. Rose et al. (2010) pointed out the increasing need for so-called end-to-end models of the marine food webs; these set-ups couple models including physical and biogeochemical processes with models for higher trophic levels. When lower-trophic-level (biogeochemical) and higher-trophic-level (fish) models are coupled, the link is typically made at the plankton level, with the former models providing food for the latter (e.g. Travers-Trolet et al., 2014b).

In stand-alone biogeochemical models that do not include higher trophic levels, zooplankton mortality is a closure term, used to return the additional biomass to detritus. It represents all processes that reduce the concentration of zooplankton and are not explicitly included in the model (for instance, predation by gelatinous organisms, predation by higher trophic levels and non-consumptive mortality). For example, Getzlaff and Oschlies (2017) used it to mimic predation and immediate egestion or mortality by higher trophic

levels. Zooplankton mortality may also form the link to fish models, when these are explicitly considered in the context of biogeochemical models (e.g. Travers-Trolet et al., 2014b).

However, there is no consensus on the form of the mortality term, linear ($\mu \cdot [Z]$, where $[Z]$ is the zooplankton concentration and μ is a mortality rate) and quadratic ($\mu \cdot [Z]^2$) being two common forms (e.g. Evans and Parslow, 1985; Fasham et al., 1990; Koné et al., 2005; Kishi et al., 2007; Aumont et al., 2015). A common argument for preferring quadratic to linear mortality is the reduction in unforced short-term oscillations (Steele and Henderson, 1992), although Edwards and Yool (2000) argue that quadratic mortality does not always remove such oscillations. A quadratic mortality term may also be interpreted as an increase in diseases because of high population densities, cannibalism or increased predation due to high densities of prey. Because it is very difficult to determine zooplankton mortality in the field, there is also no agreement on the exact value of mortality (either linear or quadratic), and this term, in practice, is often adjusted to tune the model. However, not using mortality rates based on observations may limit the capability of the model to accurately represent the zooplankton compartment (Daewel et al., 2014) and to draw predictions about the state and dynamics of the marine ecosystem (Anderson et al., 2010). Hirst and Kiørboe (2002) predicted a global mortality of copepods of 0.062 d^{-1} at 5°C and 0.19 d^{-1} at 25°C in the field. Two-thirds of such mortality is due to predation. In models, the values of the quadratic mortality rate (hereafter called μ_Z) in the literature vary over a large range, from 0.025 (Fennel et al., 2006) up to $0.25 \text{ (mmol N m}^{-3}\text{)}^{-1} \text{ d}^{-1}$ (Lima and Doney, 2004).

For the NHCS, the high variability in forcing, biogeochemistry and plankton and the high abundance of planktivorous fish, together with its economic importance, indicate the need for end-to-end models that include details of all components. However, developing such a model is challenging, and studies in this area have so far focused on either fish (Oliveros-Ramos et al., 2017) or physics and biogeochemistry (Jose et al., 2017). Given the large importance of zooplankton mortality as a link between these two model systems (Mitra et al., 2014) and the uncertainty associated with it, in this study we focus on the effects of this parameter on the biogeochemical system of the ETSP as a first step towards a fully coupled system.

In order to model the highly dynamic nature of both physical and biogeochemical processes in the ETSP, we employed a biogeochemical model specifically designed for EBUSs, coupled to a finely resolved regional circulation model. The coupled model has already been validated against oxygen, nitrate and chlorophyll (Jose et al., 2017); this configuration serves as a starting point and reference for the sensitivity experiments. In this study, we focus on the four plankton groups of the model: small and large phytoplankton and small and large zooplankton. Large phytoplankton is highly abundant near the coast of Peru in the nutrient-rich upwelling region. Towards the open ocean it is grazed down by its preda-

tor, large zooplankton; and further offshore, as conditions become oligotrophic, small zooplankton and phytoplankton take over.

In this study, we first extend the model validation by Jose et al. (2017) and assess the reliability of the large zooplankton compartment in the model by comparing it against meso-zooplankton observations obtained by net hauls. Note that in this paper we always refer to simulated phyto- and zooplankton by their size class (small or large), while observations are referred to as mesozooplankton. We then present two sensitivity experiments in which we varied the mortality rate of quadratic zooplankton mortality by $\pm 50\%$. Model sensitivity is examined with regard to concentrations of model components and inter-compartmental fluxes. Besides the overall response of the prognostic variables to an increase or decrease in zooplankton mortality, we describe how changing zooplankton mortality affects the trophic structure of plankton, with focus on the highly productive coastal domain. Finally we discuss the implications of our study for the plankton community and for modelling higher trophic levels.

2 Methods

2.1 ROMS–BioEBUS model set-up

The Regional Oceanic Modeling System (ROMS; Shchepetkin and McWilliams, 2005) is a high-resolution, free-surface, terrain-following coordinate ocean model that solves the primitive equations considering Boussinesq and hydrostatic assumptions. The Biogeochemical model for Eastern Boundary Upwelling Systems (BioEBUS), which was derived from a $N_2P_2Z_2D_2$ model from Koné et al. (2005), is coupled online to the physical part (Gutknecht et al., 2013a, b).

In this study the coupled ROMS–BioEBUS model has the same configuration as in Jose et al. (2017). It contains a small, high-resolution domain forced by a larger coarse-resolution domain, using the AGRIF (adaptive grid refinement in Fortran) 2-way nesting procedure. The small inner grid has a horizontal resolution of $1/12^\circ$ spanning from about 69 to 102° W and from 5° N to 31° S (Fig. 1). The large outer grid spans from 69 to 120° W and from 18° N to 40° S with a resolution of $1/4^\circ$. The biological processes occur in three time steps of 900 s for each physical time step of 2700 s in both domains. The two domains have 32 sigma layers with a vertical resolution of less than 5 m at the surface and decreasing to around 500 m at a maximum depth of 4500 m.

The coarse-resolution domain temperature, salinity and horizontal velocity are forced at the lateral boundaries with monthly climatological (1990–2010) SODA reanalysis (Carton and Giese, 2008). Both domains are forced at the surface with $1/4^\circ$ resolution wind velocity fields from QuikSCAT (Liu et al., 1998) and monthly heat and freshwater fluxes from COADS (Worley et al., 2005). At the lateral boundaries

Figure 1. Annually averaged sea surface temperature ($^\circ\text{C}$) and horizontal advection vectors (m s^{-1}) and location of the analysed regions (see labels) and of a vertical section for analysing plankton spatial succession (white line at 12° S). The coastal upwelling region (see Sect. 2.5) spans from the coast to about 40 to 50 km offshore.

of the coarse-resolution domain, the biogeochemical model is forced with monthly nitrate and oxygen values from CARS (Ridgway et al., 2002) and surface chlorophyll from SeaWiFS (O’Reilly et al., 1998). Phytoplankton and zooplankton boundary conditions are derived from a vertical extrapolation of the chlorophyll data. Detailed information about the boundary and initial conditions and validation of the model is available in Jose et al. (2017).

2.2 Biogeochemical model description

The evolution of a biological tracer in time is represented by Eq. (1). On the right-hand side of the equation, the first term represents the advection with the velocity vector u . The eddy and molecular diffusion is represented by the second and third terms, where K_h is the horizontal diffusion coefficient and K_z the vertical diffusion coefficient. The last term is a source-minus-sink (SMS) term due to biological processes. The full set of equations and detailed explanation about each process are available in Gutknecht et al. (2013a).

$$\frac{\partial C_i}{\partial t} = -\nabla \cdot (u C_i) + K_h \nabla^2 C_i + \frac{\partial}{\partial z} \left(K_z \frac{\partial C_i}{\partial z} \right) + \text{SMS}(C_i) \quad (1)$$

The BioEBUS model is adapted for the biogeochemical processes specific to the low-oxygen conditions of EBUSs, with some processes being oxygen dependent (see Gutknecht et al., 2013a). It has two compartments of phytoplankton, two compartments of zooplankton and two compartments of

detritus. The zooplankton and phytoplankton groups are divided into two size classes (small and large). There is not an explicit size parameter in the model; however, the compartments aim at representing the main ecological functions of the plankton community falling within each group. Hence, small phytoplankton (P_S) represents organisms smaller than about 20 μm that require low nutrients such as flagellates, while large phytoplankton (P_L) represents larger organisms such as diatoms. Similarly, small zooplankton (Z_S) simulates the role of a zooplankton community smaller than about 200 μm , such as ciliates, and large zooplankton (Z_L) represents a community larger than 200 μm , such as copepods. The two size classes of detritus (small D_S and large D_L) are produced from phytoplankton and zooplankton mortality and by release of unassimilated grazing material. The model also contains three compartments of dissolved inorganic nitrogen (NH_4^+ , NO_2^- and NO_3^-), dissolved organic nitrogen (DON), oxygen (O_2) and nitrous oxide (N_2O).

The BioEBUS model (Gutknecht et al., 2013a) includes oxygen-dependent remineralisation processes, which are divided into ammonification, nitrification and denitrification, as well as anammox, and are based on the formulations by Yakushev et al. (2007). N_2O is a diagnostic variable for model output, and its production does not affect the concentration of the other variables. It is based on the parameterisation of Suntharalingam et al. (2000, 2012), which relates the production of N_2O to the consumption of O_2 from decomposition of organic matter in oxic and suboxic conditions. O_2 concentrations depend on primary production, zooplankton respiration, nitrification and remineralisation. This model includes gas exchange of O_2 and N_2O with the atmosphere.

2.2.1 Phytoplankton

The SMS terms in the small and large phytoplankton compartments are determined by Eqs. (2) and (3), respectively:

$$\text{SMS}(P_S) = (1 - \varepsilon_{P_S}) \cdot J_{P_S}(\text{PAR}, T, N) \cdot [P_S] - G_{Z_S}^{P_S} \cdot [Z_S] - G_{Z_L}^{P_S} \cdot [Z_L] - \mu_{P_S} \cdot [P_S], \quad (2)$$

$$\text{SMS}(P_L) = (1 - \varepsilon_{P_L}) \cdot J_{P_L}(\text{PAR}, T, N) \cdot [P_L] - G_{Z_S}^{P_L} \cdot [Z_S] - G_{Z_L}^{P_L} \cdot [Z_L] - \mu_{P_L} \cdot [P_L] - w_{P_L} \cdot \frac{d}{dz} [P_L]. \quad (3)$$

Here $G_{Z_j}^{X_i}$ represents feeding rates by zooplankton (see Sect. 2.2.2); $\mu_{P_i} \cdot [P_i]$ is the mortality term, representing all not explicitly modelled phytoplankton losses; w_{P_L} is the sinking speed of large phytoplankton sedimentation, which is an additional loss term for this compartment; ε_{P_i} is the exudation fraction of primary production; and $J_{P_i}(\text{PAR}, T, N)$

is the growth rate limited by light, temperature and nutrients:

$$J_{P_i}(\text{PAR}, T, N) = \frac{J_{\max P_i} \cdot \alpha P_i \cdot \text{PAR}}{\sqrt{J_{\max P_i}^2 + (\alpha P_i \cdot \text{PAR})^2}} \cdot f_{P_i}(\text{NO}_3^-, \text{NO}_2^-, \text{NH}_4^+), \quad (4)$$

where $f_{P_i}(\text{NO}_3^-, \text{NO}_2^-, \text{NH}_4^+)$ is the growth limitation by nutrients, PAR is the photosynthetically available radiation (see Koné et al., 2005), $J_{\max P_i}$ is the maximal light-saturated growth rate which is a function of temperature and αP_i is the initial slope of the photosynthesis–irradiance (P–I) curve (Gutknecht et al., 2013a). Large phytoplankton is characterised by a steeper initial slope of the P–I curve and by larger half-saturation constants for nutrient uptake (see Table A1). Therefore, it grows better than small phytoplankton under low-light conditions, but its nutrient uptake increases more slowly as nutrient concentrations increase.

2.2.2 Zooplankton

Zooplankton increases its biomass through grazing on phytoplankton and in the case of large zooplankton also on small zooplankton. Metabolism; mortality; and, in the case of small zooplankton, predation by large zooplankton are sink terms. Predation by fish and other higher trophic levels is implicit in the quadratic mortality term. The biomass lost by metabolism and mortality is assumed to become detritus which may sink to the sediments or become remineralised, and a small fraction of zooplankton losses become ammonium and dissolved organic nitrogen, which is also subjected to remineralisation.

The SMS terms of the small and large zooplankton compartment are determined by Eqs. (5) and (6), respectively:

$$\text{SMS}(Z_S) = f1_{Z_S} \cdot (G_{Z_S}^{P_S} + G_{Z_S}^{P_L}) \cdot [Z_S] - G_{Z_L}^{Z_S} \cdot [Z_L] - \gamma_{Z_S} \cdot [Z_S] - \mu_{Z_S} \cdot [Z_S]^2, \quad (5)$$

$$\text{SMS}(Z_L) = f1_{Z_L} \cdot (G_{Z_L}^{P_S} + G_{Z_L}^{P_L} + G_{Z_L}^{Z_S}) \cdot [Z_L] - \gamma_{Z_L} \cdot [Z_L] - \mu_{Z_L} \cdot [Z_L]^2. \quad (6)$$

Here $f1_{Z_S}$ and $f1_{Z_L}$ are assimilation coefficients (see also Table A1). $G_{Z_j}^{X_i}$ is feeding rates of predator Z_j (either large or small zooplankton) on prey X_i (small and large phytoplankton and small zooplankton) calculated with the formulation by Tian et al. (2000, 2001). There is a linear loss rate accounting for basic metabolism (γ_{Z_i}) and a quadratic loss rate also referred to as mortality. The mortality parameters μ_{Z_S} and μ_{Z_L} of the reference simulation are 0.025 and 0.05 (mmol N m^{-3}) $^{-1} \text{d}^{-1}$ for small and large zooplankton, respectively, as in Jose et al. (2017) and Gutknecht et al. (2013a).

The feeding rate follows the formulation from Tian et al. (2000, 2001):

$$G_{Z_j}^{X_i} = g_{\max Z_j} \cdot \frac{e_{Z_j X_i} \cdot [X_i]}{k_{Z_j} + F_i}, \quad (7)$$

where $g_{\max Z_j}$ is the maximum grazing rate of predator Z_j , $e_{Z_j X_i}$ is the preference of predator Z_j for prey X_i , k_{Z_j} is the half-saturation constant and F_t is the total availability of food for predator Z_j . Large zooplankton responds more slowly to changes in food due to the high k_{Z_L} . In the case of large zooplankton $F_t = e_{Z_L P_S} \cdot [P_S] + e_{Z_L P_L} \cdot [P_L] + e_{Z_L Z_S} \cdot [Z_S]$, and in the case of small zooplankton $F_t = e_{Z_S P_S} \cdot [P_S] + e_{Z_S P_L} \cdot [P_L]$ (Gutknecht et al., 2013a).

2.3 Zooplankton evaluation

As noted above, this model was already validated against oxygen, nitrate and chlorophyll (Jose et al., 2017). As a complement, we here compare the large zooplankton compartment of the model, averaged from January to March, with observational data collected on RV *Meteor* cruise M93. The samples obtained during this cruise include day- and nighttime hauls with a Hydro-Bios multinet (nine nets, 333 μm mesh) between 10 February and 3 March 2013 on a transect off the Peruvian coast ($\approx 12^\circ \text{S}$; see Fig. 2f), capturing the vertical and horizontal gradient in zooplankton concentration. Samples were size-fractionated by sieving and processed according to the ZooScan method (Gorsky et al., 2010). Observations included crustaceans, chaetognaths and annelids greater than 500 μm . For model comparison we converted the observation from nighttime hauls to dry biomass according to Lehette and Hernández-León (2009) and further to nitrogen units as suggested by Kiørboe (2013). A detailed description of the zooplankton processing is provided by Kiko and Hauss (2019). Only night observations were compared since our model does not include diel vertical migration.

In both the model and observations, concentration of large zooplankton is greatest in the surface and decreases with depth (Fig. 2). At the surface, modelled concentrations are 1 order of magnitude larger than observations at almost all stations (Fig. 2). Only at station d do observations reach 1 mmol N m^{-3} , while the model exhibits maximum values close to 4 mmol N m^{-3} . At most stations, the distribution of modelled concentrations is similar to that of observed concentrations in the surface layer (upper 100 m), although model estimates are consistently higher. This is also the case when comparing against a different dataset of observations (see Supplement). Below 100 m, however, model estimates are consistently lower than the observations, which is in particular evident at the deep offshore stations (Appendix B, Fig. B1a and b). Zooplankton in our model does not consume detritus or bacteria; small zooplankton feeds on phytoplankton, and large zooplankton feeds on small zooplankton and on phytoplankton. Therefore, in contrast to observations, its presence is not expected in deep water. In summary, the model matches the observed spatial pattern of zooplankton distribution but tends to overestimate zooplankton concentration in the surface layer and to underestimate it in the

mesopelagic depths. Possible reasons for this mismatch will be discussed in Sect. 4.1.

2.4 Experimental design

To mimic changes in grazing pressure on zooplankton due to small-pelagic-fish biomass fluctuations, we followed the approach by Getzlaff and Oschlies (2017) and varied the mortality rate of each zooplankton compartment by $\pm 50\%$ in comparison to the reference scenario described by Jose et al. (2017). Thereby, an increase in mortality assumes a large consumption of zooplankton by fish, while a decrease in mortality assumes fewer fish. Because the model does not include an explicit compartment for fish, it is assumed that all zooplankton biomass consumed by fish becomes part of the detritus pool via immediate fish mortality and defecation. In reality, a fraction of the biomass is extracted from the system by the fishing industry, predation by sea birds that defecate over land and migrations.

Our model has two zooplankton compartments. In order to explore the different roles of large zooplankton as top predator and small zooplankton as grazer and prey, we performed four experiments, in which we varied the respective mortality rate of large and small zooplankton (0.05 and $0.025 [\text{mmol N m}^{-3}]^{-1} \text{ d}^{-1}$, respectively) by $\pm 50\%$:

- A_high with $1.5 \times \mu_{Z_L}$
- A_low with $0.5 \times \mu_{Z_L}$
- B_high with $1.5 \times \mu_{Z_L}$ and $1.5 \times \mu_{Z_S}$
- B_low with $0.5 \times \mu_{Z_L}$ and $0.5 \times \mu_{Z_S}$,

where μ_{Z_i} is the mortality rates of large and small zooplankton. The average nitrogen flux to detritus due to large zooplankton mortality over the upper 100 m depth near the coast of Peru (coastal upwelling region; see Sect. 2.5 and Fig. 1) in the reference scenario is $3.1 \text{ mmol N m}^{-2} \text{ d}^{-1}$ ($\mu_{Z_L} \cdot [Z_L]^2$, Fig. 3). Neglecting any non-linear and feedback effects within the model, a 50% change in the mortality rate would result in a change in zooplankton loss due to mortality of $1.55 \text{ mmol N m}^{-2} \text{ d}^{-1}$. It is thus a conservative value, compared to a change of $5 \text{ mmol N m}^{-2} \text{ d}^{-1}$ that anchovy population fluctuations could theoretically exert, as estimated in Sect. 1.

All model experiments and the reference scenario were spun up for 30 climatological years. Annual means of the state variables and nitrogen fluxes from the last climatological year of the high-resolution domain were analysed.

2.5 Model analysis

The ETSP is highly dynamic at temporal and spatial scales, with nutrient-rich cold water near the coast of Peru and oligotrophic regions offshore. Therefore, we analysed three different regions: the “full domain” without boundaries (F),

Figure 2. (a–e) Zooplankton concentrations (mmol N m^{-3}). Lines indicate modelled large zooplankton concentrations in the reference scenario and experiments B_high and B_low averaged from January to March. Shaded area shows observed nighttime mesozooplankton biomass concentrations over the sampled depth intervals (m). Observations are lower than $0.1 \text{ mmol N m}^{-3}$ below 200 m; thus they have not been included. For a plot including deep-water observations, please see Appendix B, Fig. B1, and Fig. 4 in Kiko and Hauss (2019). Bottom right: modelled large zooplankton biomass concentration at the surface in the reference scenario (mmol N m^{-3}) and locations where observations were collected.

Figure 3. Nitrogen flux from large (a) and small (b) zooplankton to detritus due to zooplankton mortality, integrated over the upper 100 m of the water column in the reference scenario ($\text{mmol N m}^{-2} \text{ d}^{-1}$).

an “oligotrophic” region (O) offshore and the “coastal upwelling” region (C) near the Peruvian coast (Fig. 1). Since the upwelling system of Peru is quite heterogeneous with lots of mesoscale processes, we restricted the C region to the very

coastal upwelling area, where the concentration of large phytoplankton is high, up to about 40 to 50 km offshore. Region O was picked to be as far as possible from the nutrient-rich areas along the Equator and along the coast but apart from the domain boundary to avoid boundary effects. For most of our analysis, percentage relative differences between the reference scenario and the other scenarios were calculated. In addition, we analyse the development of plankton succession from the coast of Peru towards the open ocean at 12° S (Fig. 1, white line). Because plankton concentrations are negligible below 100 m depth and we are mainly interested in the plankton community, we focus most of our analysis on the upper water layers. For our analysis we therefore integrate or average plankton concentrations over the upper 100 m or, in the case of shallower waters, down to the seafloor. Also, all analyses in our study take into account only annual averages. However, we recognise that there is high temporal variability in the NHCS (see Appendix C and Supplement).

3 Results

We first provide an overview of the general performance of the reference scenario, with respect to the different model components and biogeochemical provinces (Sect. 3.1). We then investigate their response to changes in zooplankton mortality and the response of the plankton ecosystem structure (Sect. 3.2). The coastal upwelling region (C) is especially productive and the habitat of the largest aggregations of small pelagic fish, whose temporal variability inspired this study. Therefore, in Sect. 3.3 we place special emphasis on this region. Finally, we investigate the response of the zooplankton losses due to mortality in the experiments, in order to understand whether the model structure buffers or increases the effect of varying the zooplankton mortality rate on such a term (Sect. 3.4). This would give us an insight into potential feedbacks to higher trophic levels.

3.1 Biogeochemistry and plankton distribution in the reference scenario

In this section we describe the concentrations of the inorganic and organic compartments in our model reference scenario, averaged between a 0 and 100 m depth (Fig. 4) unless otherwise specified. Oxygen concentrations increase offshore, with an average of $226.6 \text{ mmol O}_2 \text{ m}^{-3}$ in the oligotrophic region (O) compared to $69.7 \text{ mmol O}_2 \text{ m}^{-3}$ in the coastal upwelling region (Fig. 4). The concentration decreases further below 100 m, reaching an average of $5.3 \text{ mmol O}_2 \text{ m}^{-3}$ between 100 and 1000 m in the coastal upwelling region (C). Nitrate is the most abundant nutrient all over the domain, ranging from 0.6 in O to $21.7 \text{ mmol N m}^{-3}$ in C. On the other hand, ammonium and nitrite are only 0.8 and $3.2 \text{ mmol N m}^{-3}$ in C, respectively (Fig. 4). Please refer to Jose et al. (2017) for a further in-depth analysis of biogeochemical tracers in the reference scenario.

Phyto- and zooplankton are generally absent in the deep water. In the surface layer between a 0 and 100 m depth (Fig. 4), phytoplankton is clearly favoured by nutrient-rich coastal upwelling, where total phytoplankton reaches $0.93 \text{ mmol N m}^{-3}$ on average, compared to $0.25 \text{ mmol N m}^{-3}$ in the oligotrophic region (Fig. 4). Total detritus follow the concentration trend of plankton, with 0.26 in C and only 0.03 in O.

When zooming into the coastal region (Fig. 5), large phytoplankton exhibits a sharp peak near the coast which drops offshore. Moving further offshore, large zooplankton peaks at the decline in the large phytoplankton peak, followed by increased concentrations of small phytoplankton. Given the (Ekman-driven) transport of surface waters (Fig. 1) this spatial pattern might be interpreted as a form of succession as the water is advected offshore. In general, modelled concentrations of large zooplankton are high not only in the coastal upwelling region (Sect. 2.3) but also in large parts of the do-

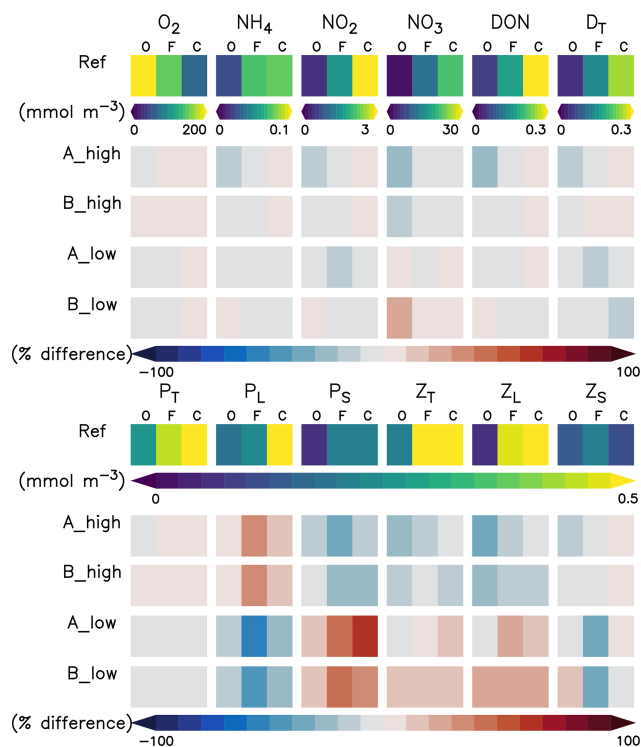

Figure 4. Annually, spatially (oligotrophic (O) region, full domain (F) and coastal upwelling (C) region; see Fig. 1 for further reference) and depth-averaged (0–100 m) concentrations (mmol N m^{-3} or $\text{mmol O}_2 \text{ m}^{-3}$) of the biogeochemical prognostic variables in the model reference scenario and normalised percent difference between the reference scenario and experiments. *P* is phytoplankton; *Z* is zooplankton; *D* is detritus; DON is dissolved inorganic nitrogen; T is total; L is large; S is small.

main (Fig. 4), except for in the oligotrophic south-western region (Fig. 4).

The growth rate of phytoplankton is limited by temperature, nutrients and light (see Eq. 4). Hence, the spatial pattern of plankton near the coast can be explained by the competitive advantage of large phytoplankton in deep water due to its steeper initial slope of the P–I curve (see Appendix A, Table A1), eutrophic conditions in the nutrient-rich upwelling water and relatively low predation due to the lack of large zooplankton. This opens a loophole for large phytoplankton to grow in the upwelling waters. As water is transported offshore (Fig. 1), large zooplankton starts to grow and grazes on large phytoplankton. More oligotrophic sunlit conditions even further offshore favour small phytoplankton growth at the surface. Therefore, this first analysis reveals spatial segregation and succession from the coast to offshore waters. These patterns are caused by the model's parameterisation of plankton groups and their mutual interactions.

Figure 5. Zonal distribution of surface plankton concentrations at 12° S annually averaged in the reference and the two B scenarios, respectively. The location of this section is indicated as a white line in Fig. 1.

3.2 Response to zooplankton mortality

When changing zooplankton mortality, the inorganic variables (Fig. 4) are not noticeably affected by the experiments.

Plankton responds very similarly to changes in mortality in experiments A and B (Fig. 4 and Appendix D, Fig. D1). Phytoplankton and large zooplankton follow the same direction of response in all regions: concentrations of large zooplankton decrease in the high mortality scenario and increase in the low mortality scenario, as could be expected. Large phytoplankton responds inversely to large zooplankton, evidencing a top-down control of its main grazer. On the other hand, the response of small phytoplankton is inverse to that of large phytoplankton. In contrast, small zooplankton shows an asymmetric response to changes in mortality, as it mainly decreases in the low mortality scenarios but responds only weakly in the high mortality scenarios (Fig. 4 and Appendix D, Fig. D1).

The spatial plankton distribution along the transect (Fig. 5) remains the same when zooplankton mortality changes, but the absolute concentrations of each compartment change. In all scenarios large phytoplankton peaks close to the coast. When large zooplankton concentrations are reduced because of its higher mortality in experiment B_high, the large phytoplankton peak increases (Fig. 5, right). Similarly, large phytoplankton decreases with lower zooplankton mortality, due to higher grazing of zooplankton on phytoplankton (Fig. 5, left). This pattern is also similar in experiments A. Because the largest effects occur in the very productive coastal region (C), in the following section we narrow our analysis to this domain.

3.3 Effects on the food web in the coastal domain

An increase in zooplankton mortality causes only small changes in total primary production in the coastal upwelling region (C), but the partitioning between the two phytoplankton groups changes (Fig. 6). In particular, total primary productivity of the system is increased by 3.9 % in B_high and reduced by 5.5 % in B_low. Large phytoplankton is the dom-

inant group. However, its productivity increases by about 19 % in B_high and decreases by 22 % in B_low; i.e. its changes are much more pronounced than the overall phytoplankton response. Because small phytoplankton shows an inverse response in production, this dampens the change in total primary production. Thus, a low zooplankton mortality favours small phytoplankton and its growth, and a high mortality favours large phytoplankton; changes in both phytoplankton groups result in a weak response of total primary production.

Experiment B_high exhibits the highest total plankton biomass in the upper 100 m of the upwelling system ($112.6 \text{ mmol N m}^{-2}$, Fig. 6), which is mostly concentrated in the large phytoplankton compartment ($59.43 \text{ mmol N m}^{-2}$). In this experiment the main pathway of nitrogen transfer to large zooplankton is via its grazing on large phytoplankton ($6.77 \text{ mmol N m}^{-2} \text{ d}^{-1}$). As mortality decreases, small phytoplankton and large zooplankton gain biomass. Large phytoplankton grazing remains the main nitrogen source for large zooplankton. However, large zooplankton consumption of small phytoplankton is almost 3 times higher in B_low than in B_high (Fig. 6). Thus, a reduction in mortality causes a switch in the diet of large zooplankton, from mainly large phytoplankton to a diet that consists of more than one-quarter small phytoplankton.

Small zooplankton biomass decreases by $\sim 0.4 \text{ mmol N m}^{-2}$ (about 5 % of the reference value) in B_low, but it only increases by $0.15 \text{ mmol N m}^{-2}$ (about 2 %) in B_high (Fig. 6). Despite the changes in small zooplankton biomass, the consumption of its biomass by large zooplankton remains approximately the same in all experiments, resulting in a higher proportional biomass loss of small zooplankton in scenario B_low. Hence, predation by large zooplankton as well as competition for food negatively affects small zooplankton. Under high mortality conditions, the availability of large phytoplankton as food increases (Fig. 6). However, small phytoplankton, the preferred prey of small zooplankton, declines as explained above. Such

Figure 6. Concentrations (mmolN m⁻²) and nitrogen fluxes (mmolN m⁻² d⁻¹) between plankton compartments (small and large phytoplankton P_S and P_L and small and large zooplankton Z_S and Z_L, respectively) integrated over the upper 100 m or up to the seafloor if shallower than 100 m and averaged over latitude and longitude in the coastal upwelling region (see Fig. 1). SZ and SP indicate the sinks which include phytoplankton mortality, zooplankton metabolism, large phytoplankton sedimentation, unassimilated primary production and unassimilated grazing (Gutknecht et al., 2013a).

Figure 7. Percentage normalised difference in the nitrogen flux from large and small zooplankton to detritus due to zooplankton mortality, integrated over the upper 100 m of the water column, between experiment B_{high} and experiment B_{low} and the reference scenario (see Fig. 3 for the reference scenario).

antagonistic effects on small zooplankton buffer its response in this scenario.

3.4 Zooplankton losses due to mortality response

In this section, we describe the response of the nitrogen loss due to mortality, also referred to as the quadratic mortality term ($\mu_{Z_i} \cdot [Z_i]^2$; see Eqs. 5 and 6). The integrated $\mu_{Z_i} \cdot [Z_i]^2$ in the reference scenario was provided in Sect. 2.4, Fig. 3. In experiment B, $\mu_{Z_S} \cdot [Z_S]^2$ and $\mu_{Z_L} \cdot [Z_L]^2$ exhibit different behaviours. In the coastal upwelling region, both $\mu_{Z_S} \cdot [Z_S]^2$ and $\mu_{Z_L} \cdot [Z_L]^2$ increase in B_{high} and decrease in B_{low} (Fig. 6). However, the relative response of $\mu_{Z_L} \cdot [Z_L]^2$ is mild and fluctuates between $\pm 30\%$ outside the oligotrophic area (Fig. 7). In contrast, $\mu_{Z_S} \cdot [Z_S]^2$ exhibits a clear relative increase all over the domain in B_{high}, and a decrease in B_{low}. The moderate response of large zooplankton loss can be attributed to the combined effects of changes in zooplankton concentration ($[Z_L]$) and changes in the mortality parameter (μ_{Z_L}), which we varied by $\pm 50\%$ in this study. Large zooplankton concentration increases when μ_{Z_L} is decreased, and vice versa. This opposite trend buffers the effect of a change in μ_{Z_L} . On the other hand, small zooplankton concentration ($[Z_S]$) changes in the same direction as μ_{Z_S} , due to the combined effects of changes in its concentration, due to grazing pressure exerted by large zooplankton and competition for food with this group, and changes in μ_{Z_S} .

To summarise, increasing and decreasing zooplankton mortality by 50 % generates a rearrangement of the plankton ecosystem; however, the overall changes in the large zooplankton loss are not as high as would be expected from a change in the mortality rate alone. This might buffer the system once the biogeochemical model is coupled to a model of higher trophic levels.

4 Discussion

4.1 Constraining the zooplankton compartment

An increasing need for the development of end-to-end models has generated interest in using results of biogeochemical models as forcing for higher-trophic-level models (fish, macroinvertebrates and apex predators) (see Tittensor et al., 2018, for a review). In a one-way coupling set-up, the biomass of plankton available as food for higher trophic levels has been adjusted during calibration of the latter, reducing the amount of plankton that is available for fish consumption (e.g. Oliveros-Ramos et al., 2017; Travers-Trolet et al., 2014b). However, for two-way coupling set-ups, this adjustment of the available plankton biomass could buffer the effect of higher trophic levels on lower trophic levels (e.g. Travers-Trolet et al., 2014b). Biogeochemical models can produce a wide range of output depending on their parameter values (Baklouti et al., 2006) and their non-linearity. For example, a quadratic zooplankton mortality exacerbates the reduction in zooplankton biomass when concentrations are very high and prevents its extinction at very low concentrations. In addition, the multiple-resource form of the Holling type-II grazing function allows the predator to modify its grazing preference towards the most abundant prey (Fasham et al., 1999). Finally, Lima et al. (2002) noted that coupled physical and food web models can transition from equilibrium to chaotic states under even small changes in their parameters. Few studies have aimed to understand such behaviour (Baklouti et al., 2006) and examined the sensitivity of the model to parameters (Arhonditsis and Brett, 2004; Shimoda and Arhonditsis, 2016). Our model study was partly motivated by the uncertainty associated with the zooplankton mortality. Indeed our model showed that a small alteration in the mortality parameter (small compared to the wide range of values that have been used for this parameter in different biogeochemical models) can strongly affect the mass flux within the simulated ecosystem. Hence, there is an increasing need for accurate plankton representation in biogeochemical models without dismissing other compartments, such as nutrients or oxygen. Nevertheless, lack of data for validation especially of higher trophic levels is a common problem for biogeochemical models of the northern Humboldt Upwelling System (Chavez et al., 2008). Oxygen, chlorophyll and nitrate in our model have been evaluated previously (Jose et al., 2017). Here we presented the first attempt to compare

the large zooplankton compartment of the ROMS–BioEBUS ETSP configuration with mesozooplankton observations.

At the surface, zooplankton concentrations simulated by our model in the reference scenario are 1 order of magnitude higher than observations at most stations. However, sampling in the upper 10 m depth may be impacted by water disturbance by the ship adding additional errors to the measurements. The match to observations improves with depth. Modifying the mortality rate by +50 % (–50 %) produced only a change of –12 % (+19 %) in large zooplankton concentration, indicating that either the induced changes in mortality rate were not large enough or this parameter is not overly influential in improving the model fit to observations. Systems with a non-density-dependent, or linear, mortality rate respond to perturbations in a “reactive” way, as defined by Neubert et al. (2004), drifting away from equilibrium, in contrast to systems with density-dependent closure terms which tend to buffer the perturbations (Neubert et al., 2004). Therefore, we might have expected a stronger impact if we had manipulated the linear closure term of the model, or metabolic losses (see Sect. 2.2.2), rather than the quadratic term. For an average nitrogen flux due to large zooplankton mortality of 2.2, 3.1 and 3.52 mmol N m^{–2} d^{–1} and large zooplankton integrated concentrations of 46.36, 38.82 and 34.17 mmol N m^{–2} in the coastal upwelling region (see Sect. 3.3), the mortality rate would be 0.04, 0.08 and 0.1 d^{–1} in scenarios B_low, reference and B_high, respectively. In all cases the values are lower than the 0.19 d^{–1} estimated by Hirst and Kiørboe (2002) for copepods in the field at 25 °C. The closest scenario to observations is B_high where the mortality rate is only about half of the estimate by Hirst and Kiørboe (2002). This is also the scenario that better resembles mesozooplankton observations, since it exhibits the lowest concentrations. On the other hand, the mortality rate estimated for the reference scenario (0.08 d^{–1}) is closer to the 0.065 d^{–1} estimation by Hirst and Kiørboe (2002) at 5 °C. This is considerably lower than the temperature in our modelled region (see Fig. 1). Note, however, that zooplankton mortality in our model does not depend on temperature.

Some part of the mismatch between model and observations might be related to how both data types are generated. Therefore, a direct comparison between model and observations has to be viewed with some caution. In our model, large zooplankton acts as a closure term which is adjusted to balance the biomass and nitrogen flux to other compartments and does not resemble a specific set of species. Its parameters (maximum grazing rate, feeding preferences, etc.) are meant to represent larger, slow-growing species with a preference for diatoms. As such, they might not be directly comparable to the observed groups. The observations, on the other hand, are susceptible to sampling errors such as net avoidance and do not cover the whole taxonomic and size spectrum of mesozooplankton. For instance, no gelatinous organisms are accounted for, which may account for an important fraction of the wet biomass (Remsen et al., 2004);

only mesozooplankton greater than 500 μm is considered in the sampling (Kiko and Hauss, 2019); and fragile organisms, such as Rhizaria, are not quantitatively sampled by nets (Biard et al., 2016). Therefore, the observations might be biased low in comparison to the model. Furthermore, a lack of an explicit size term in the model limits a direct comparison with observations because these depend on the mesh size of the sampling net. Finally, given the above-mentioned rather pragmatic parameterisation especially of zooplankton growth and loss rates, it is very likely that the model could be improved by a tuning or calibration exercise that targets a good match between observed and simulated zooplankton concentrations. Both the mortality estimation by Hirst and Kiørboe (2002) and the zooplankton observations in the field suggest that further tuning of the model should lean towards higher mortality rates. Nevertheless, this may require the further tuning of other parameters. Despite the complexity of the model, the considerable uncertainty in model parameters and the sparsity of observations that can constrain these parameters, this is a complex task (see e.g. Kriest et al., 2017). Therefore, we have refrained from this effort for the present but aim at providing a better-calibrated model in the future.

The spatial variability between different profiles of zooplankton is greater in the observations than in the model, and the variability in concentrations within each single profile is much larger than the differences between the modelled mortality scenarios (Fig. 2). Several sources of variability are not accounted for in the model as it only simulates the most relevant processes in the system. We employ a climatological model which aims at simulating the average dynamics over several years, dismissing interannual variability. Furthermore, we here compare a 3-month average from January to March, while observations provide only a snapshot of a highly dynamical system. In addition, we only compared our simulated zooplankton against night observations because in our model zooplankton is always active at the surface. In reality, zooplankton is known to perform diel vertical migrations (DVMs), which could increase the export flux to the deep ocean (Aumont et al., 2018; Archibald et al., 2019; Kiko and Hauss, 2019; Kiko et al., 2020). The lack of DVM could affect the export of organic matter to greater depths and therefore the biogeochemical turnover at the surface. Zooplankton likely also experiences lower mortality at depth (Ohman, 1990); however, off Peru these benefits might be counterbalanced by reduced oxygen availability and the concurrent metabolic costs. These obstacles for comparing zooplankton models with observations had already been described by Mullin (1975) more than 4 decades ago: (a) “the zooplankton is a very heterogeneous group, defined operationally by the gear used for capture rather than by a discrete position in the food web” (Mullin, 1975). (b) Zooplankton is irregularly distributed in space, not necessarily following physical features. (c) Adult stages of some zooplankton groups perform vertical migrations (Mullin, 1975).

To summarise, some biases and mismatches between model and observations remain; given the uncertainties and episodic nature associated with the observations and their correspondence to their model counterparts, further studies will be necessary to more precisely calibrate the model. For a complete model evaluation, however, the small zooplankton compartment should also be evaluated against microzooplankton samples. The high mortality scenario, B_high, is the one that is closest to the observations, due to producing the smallest concentrations of large zooplankton at the surface. However, changing this parameter was obviously not enough to match the observations. In fact, in our model an increase of 50 % in the mortality rate produced only an increase of 14 % ($0.4 \text{ mmol N m}^{-2} \text{ d}^{-1}$) in large zooplankton mortality loss (see Sect. 3) because of the high non-linearity of the model. Indeed, potential changes in zooplankton losses of $5 \text{ mmol N m}^{-2} \text{ d}^{-1}$, derived by fluctuations in anchovy stocks and grazing pressure (see Sect. 1), point towards much larger values for the mortality rate. An even stronger increase in the zooplankton mortality rate (e.g. Lima and Doney, 2004, applied a 5-times-larger value), along with a subsequent adjustment of other parameters, may be necessary to approach observed values. In addition, complementary observations with other sampling methods could provide a better estimation of mesozooplankton concentrations for tuning the model.

4.2 Zooplankton mortality and the response of the pelagic ecosystem

Our model study showed the strongest response of the ecosystem to changes in the mortality rate in the highly productive coastal upwelling. Here, the response of the model ecosystem was mainly driven by large zooplankton. This can be concluded from the close similarity of model solutions A_high and B_high, as well as of A_low and B_low (see Appendix D). The mortality term for small zooplankton played a lesser role; in addition to the direct effect of the mortality rate, this compartment was also affected by grazing by, and competition with, large zooplankton. Large zooplankton fluctuations due to mortality directly affected large phytoplankton through grazing. Small phytoplankton, on the other hand, was affected by grazing but also by competition with large phytoplankton. Changing the mortality rate produced little effect on the mass loss of large zooplankton due to mortality; however, it altered the nitrogen pathways along the trophic chain and ultimately the concentrations of most plankton groups, albeit in different ways, depending on the direction of change. Under conditions of high zooplankton mortality the food chain is dominated by nitrogen transfer from large phytoplankton to large zooplankton, the classical food web attributed to highly productive upwelling systems (Ryther, 1969). When zooplankton mortality is reduced, large zooplankton increases its consumption of small phytoplankton, taking over the role of small zooplankton.

In our model, large zooplankton has a competitive advantage by feeding on its competitor, small zooplankton, a strategy that was also found to evolve in simple ecosystem models as an advantageous alternative to direct competition (Cropp and Norbury, 2020). We find that under low mortality conditions, this advantage increases. The importance of competition is further evidenced in the changes in small phytoplankton concentrations in the coastal upwelling region. These were partly driven by changes in the availability of resources arising from fluctuations in large phytoplankton concentrations, which constitute the dominant group in the coastal upwelling. Natural selection, competitive exclusion and different resource utilisation strategies, together with bottom-up forcing by the physical processes in the environment, can shape the plankton community in global models (Follows et al., 2007; Dutkiewicz et al., 2009; Barton et al., 2010) and indicate bottom-up effects on the phytoplankton community. On the other hand, Prowe et al. (2012) showed that variable zooplankton predation can increase phytoplankton diversity by opening refuges for less competitive phytoplankton groups and thus exert top-down effects. In our study, the biological interactions between two phytoplankton groups, mainly competition for resources (bottom-up), are additionally affected in a top-down manner by changes in zooplankton concentrations.

The processes driving the ecosystem response in our regional study are dominated by trophic interactions among the size classes of phytoplankton and zooplankton. We found a top-down-driven response affecting mainly the plankton compartments of the model. The direction of the total zooplankton and total phytoplankton change is determined by the large zooplankton and large phytoplankton groups. Small zoo- and phytoplankton buffer the response when they present opposite trends to their larger counterparts (Table 1). In the following, we will compare our results with a similar study by Getzlaff and Oschlies (2017).

Getzlaff and Oschlies (2017), in their sensitivity study, modified the zooplankton mortality by $\pm 50\%$ in a global biogeochemical model with a spin-up time of 300 years. Their model has only one zooplankton size class with a quadratic mortality term. For their analysis, Getzlaff and Oschlies (2017) evaluated three regions: the whole domain, also referred to here as “global”; the region from 20°S to 20°N which in this coarse-resolution model is mainly an oligotrophic region and is referred to as “tropics”; and the region south of 40°S where nutrient concentrations are high and is named “Southern Ocean”. After the model spin-up, global zooplankton biomass changes by about $- (+)5\%$, and phytoplankton biomass by about $+ (-)1\%$ in the high (low) mortality scenario (Getzlaff and Oschlies, 2017, their Fig. 2). In contrast, in our study, total zooplankton averaged over the full domain decreases (increases) by -11% (10%), and total phytoplankton changes by about $+ (-)6\%$ in the high (low) mortality scenario (Fig. 4 and Table 1). Hence, the effects of changing zooplankton mortality follow the same trend in

Table 1. Qualitative comparison of the response of total, large and small zooplankton (Z_T , Z_L , Z_S) and phytoplankton (P_T , P_L , P_S) to a 50% higher and lower zooplankton mortality parameter in our experiments B, with the results from Getzlaff and Oschlies (2017) (Z_{GO} , P_{GO}). Full, oligotrophic and coastal upwelling refer to the regions in our study (see Fig. 1) integrated over the upper 100 m; global, Southern Ocean and tropics refer to the study by Getzlaff and Oschlies (2017, their Figs. 2 and 3 at year 300). We grouped together global and full because both refer to the whole model domain in each of the two studies. Similarly, oligotrophic and tropics refer to regions characterised by low nutrient concentrations, and coastal upwelling and Southern Ocean are both regions with high nutrient concentrations.

	Z_T	P_T	Z_L	P_L	Z_S	P_S	Z_{GO}	P_{GO}
Full and global								
High	-	+	-	+	-	-	-	+
Low	+	-	+	-	-	+	+	-
Oligotrophic and tropics								
High	-	+	-	+	-	+	-	-
Low	+	-	+	-	+	+	+	+
Coastal upwelling and Southern Ocean								
High	-	+	-	+	+	-	+	+
Low	+	-	+	-	-	+	-	-

both studies, but they are slightly milder in the study by Getzlaff and Oschlies (2017). At the regional scale, the responses in the study of Getzlaff and Oschlies (2017) have a feedback from lower trophic levels, either to phytoplankton in the nutrient-replete region or all the way to nutrients in the oligotrophic region. Therefore, the biomass of both zooplankton and phytoplankton is ultimately bottom-up affected. This is evidenced by a change in zooplankton and phytoplankton concentrations in the same direction (Getzlaff and Oschlies, 2017, their Fig. 3). On the other hand, although our study also exhibits a feedback from phytoplankton to zooplankton, the strongest driver remains the top-down predation of zooplankton on phytoplankton (Table 1).

The regional differences between our study and that by Getzlaff and Oschlies (2017) can likely be explained by the different model structures and experimental set-ups, namely the number of phyto- and zooplankton compartments, different timescales considered for model simulation and analysis, and the spatial domain: while Getzlaff and Oschlies (2017) applied a global biogeochemical model with just one size class of phyto- and zooplankton, simulated until near a steady state, our regional model study applies a more complex biogeochemical model with a strong seasonal cycle (see Appendix C), simulated for only 30 years and constantly forced at the boundaries. Further, the short few-year timescale of our model simulations might have prevented the effects of changed zooplankton mortality from propagating to deeper

water layers which contain the largest concentrations of nutrients. Finally, the region modelled in our study is spatially already very dynamic at the mesoscale resolution, as evidenced by well-defined plankton spatial succession from the coast of the continent towards the open ocean. The phytoplankton bloom, which develops closest to the coast and then is offset while water is transported offshore, can be explained by an imbalance between sources and sinks, triggered by changing environmental conditions. For example, Irigoien et al. (2005) applied the concept of “loopholes”, proposed by Bakun and Broad (2003) to explain fish productivity and recruitment success, to phytoplankton: according to their concept, phytoplankton blooms are formed when environmental conditions open a loophole in the plankton community of a mature ecosystem. Then, particularly phytoplankton species that are able to escape microzooplankton predation are those that will take advantage of the loophole and bloom (Irigoien et al., 2005). Our model results suggest that similar processes occur. Low concentrations of large zooplankton allow large phytoplankton to bloom near the coast. While the water is advected offshore, zooplankton growth and grazing offset the bloom. Observations by Franz et al. (2012) also reported spatial succession with large diatoms abundant in the coastal upwelling region being replenished by nanophytoplankton offshore. However, they propose silicate as the limiting nutrient offsetting the diatoms’ peak, which is not present in our model. Furthermore, such succession is not unique to the NHCS but a characteristic feature of upwelling regions (Hutchings, 1992). We note that in the present configuration the BioEBUS model does not include any temperature-dependent zooplankton grazing rate. We expect that, if this were implemented, the loophole for phytoplankton growth in the cold waters of the coastal upwelling region would even be widened, amplifying the spatial succession we observed. However, temperature might also affect zooplankton metabolism, with colder temperatures decreasing its loss rates, which could in turn mute these effects again. On the other hand, the global model by Getzlaff and Oschlies (2017) does not resolve mesoscale processes. Furthermore, while they divided their study into the tropics, as an oligotrophic region, and the Southern Ocean, as an upwelling region, the upwelling system off Peru in the eastern tropical South Pacific is a nutrient-rich area. For all of this, we based our comparison on similarities in the nutrient concentration (high nutrients, oligotrophic and whole domain), rather than on geographic overlap.

In Getzlaff and Oschlies (2017), the zooplankton loss due to mortality is not provided. However, it can be calculated from the zooplankton concentration and mortality rate. Assuming integrated zooplankton biomasses at year 300 (Getzlaff and Oschlies, 2017, their Fig. 2) of 98, 93 and 89 Tg N in the low mortality, reference and high mortality scenarios, respectively; mortality parameters of 0.03, 0.06 and 0.09 (mmol N m³)⁻¹ d⁻¹; and a quadratic mortality term, then there is a difference of -44.5 % and 37.4 % in the zoo-

plankton loss due to mortality between the low and reference scenario and between the high and reference scenario, respectively. As shown in Sect. 3.4, the mortality rate in our study is also smaller than the ± 50 % changes that would be expected from a change in the mortality parameter of ± 50 % (see Sect. 2.4). The non-linearity of both global and regional models seems to reduce the effect of changes in the mortality parameter on zooplankton loss.

In summary both studies show a similar global response to changes in zooplankton mortality, driven by zooplankton preying on phytoplankton. Two zooplankton and phytoplankton size classes present opposite trends in our studies, buffering the overall response. Nevertheless, the relative changes in total zooplankton and total phytoplankton are on the same order of magnitude as in Getzlaff and Oschlies (2017) and even slightly higher. Regionally different feedbacks operated in the two models, possibly due to the specific set-up of each study, spin-up time and resolution. Finally, the relative change in the zooplankton loss due to mortality is smaller than the expected ± 50 % in both studies.

4.3 From plankton to higher trophic levels

In our study, we changed the zooplankton quadratic mortality, which could be regarded as the effect of a predator targeting highly aggregated zooplankton populations, or whose concentration closely follows that of zooplankton. This can be viewed as a way to parameterise the effect of changing fish abundance on the biogeochemistry of the system. In this case, a low zooplankton mortality implies fewer small pelagic fish (such as anchovies and sardines), while a high zooplankton mortality implies a higher abundance of such fish. Further, our experiments are based on two different assumptions: one where small pelagic fish feed only on large zooplankton (experiments A) and one where they feed on and affect the mortality of both large and small zooplankton (experiments B).

The diet of anchovy is still under debate. While previous studies had considered that anchovies feed mainly on phytoplankton, Espinoza and Bertrand (2008) concluded that anchovies feed on zooplankton, especially euphausiids and copepods. Furthermore, the diet of anchovy seems to be more flexible than previously considered (Espinoza and Bertrand, 2008). For instance, the anchovy collapse in 1972 was correlated with a shift from a population feeding mostly on phytoplankton to a southern population feeding on zooplankton (Hutchings, 1992). On the other hand, small zooplankton groups such as ciliates have been reported as a minor component of anchovy diet (Table 5 in Espinoza and Bertrand, 2008). Thus, experiments A are more likely to resemble the fluctuations in anchovy populations. On the other hand, sardines, with their finer gill rakers, obtain most of their nutrition from microzooplankton (van der Lingen et al., 2006). Although currently sardines are not as abundant as anchovies off Peru, historically they have also built up large concen-

trations and strong fluctuations over time have been observed (Lluch-Belda et al., 1989; Rykaczewski and Checkley, 2008). Thus, when also considering sardine populations and feeding modes, experiments B (simultaneous mortality change in both large and small zooplankton) might be more appropriate to parameterise the effects of changed fishing mortality on lower trophic levels.

Although the quadratic mortality rate is constant over the entire domain, the fractional loss rate by zooplankton mortality ($\mu_{Z_i} \times Z_i; \text{d}^{-1}$) varies over the domain because of changes in zooplankton concentration. This might mimic spatially variable grazing pressure by fish. However, our experimental set-up might be too simple to investigate the detailed response of predator–prey relationships. We partly tried to avoid conclusions that are too general by focusing our analysis on the coastal upwelling region off Peru, since anchovies are highly concentrated in this region (Checkley et al., 2009). In addition, we neglected any feedback effects between zooplankton and their predator fish. A more detailed model set-up, as, for example, in coupled biogeochemical–fish models (Oliveros-Ramos et al., 2017), would help to elucidate the specific trophic interactions in this region and their response to environmental changes and changes in fishing pressure.

Finally, we note that the parameterisation of fish predation in our study implies that all organic matter is transferred from zooplankton straight to the detritus compartment and then remineralised. In the real world, it is stored as fish for some time until the fish defecate or die (Allgeier et al., 2017). In an equilibrium state this would not be a problem since there is a constant turnover of nutrients. In a non-equilibrium state, the time that nutrients spend as part of larger animals' biomass would increase the gap between nutrient consumption by phytoplankton and their replenishment, affecting phytoplankton growth rate and potentially the blooming timing. However, this should not be a problem in the coastal upwelling region because nutrients are highly concentrated here. This is not the case for the oligotrophic region although, in our study, this region presents the weakest response. Furthermore, small pelagic fish concentrate mainly in the highly productive upwelling region rather than in the oligotrophic waters offshore. On the other hand, fish and larger animals are highly mobile and do not constantly drift by advection as nutrients and plankton do. Therefore, migrations transport nutrients and organic matter in and out of the region in a horizontal (McInturf et al., 2019; Varpe and Fiksen, 2005; Williams et al., 2018) and vertical (Davison et al., 2013; Lavery et al., 2010) fashion. Such nutrient dynamics over time and space driven by higher trophic levels can be further explored either in explicitly coupled end-to-end models or in an implicit way similarly to in our study.

5 Conclusions

In summary, our study showed that changes in zooplankton mortality can have a strong impact on the trophic interactions between the plankton compartments of the model. Such changes are meant to mimic variations in the abundance of planktivorous fish in the system. Large zooplankton mortality, as the top predator in the model, is the main driver of the planktonic food web response in the model. Changes in the mortality rate of small zooplankton, which may resemble fluctuations in the sardine populations, are masked when large zooplankton mortality also changes. The zooplankton high mortality scenario, which mimics an increase in planktivorous fish, generates a shorter food web where most of the nutrients are taken up by large phytoplankton. In the low mortality scenario, the biomass of small phytoplankton increases and a longer food chain where nitrogen reaches large zooplankton through consumption of small zooplankton is favoured (Sect. 3.3). Our 50 % mortality changes are small compared to changes expected from the population fluctuations that small pelagic fish have historically experienced in the NHCS (Sects. 1 and 2.4). In this study we were interested in the possible top-down effects of those fluctuations on the biogeochemistry, rather than on their causes. However, in a highly bottom-up-driven system, it is important to be cautious and conservative when evaluating top-down scenarios. A fully coupled end-to-end ecosystem model explicitly including fish (as by, for example, Travers-Trolet et al., 2014b) would allow the representation of the effect of temporal and spatial variability of fish. It would also allow for a specialised targeting of fish food and for including the bottom-up effect of changing zooplankton concentration on fish populations, as well as their top-down effect and its potential consequences for the entire ecosystem. However, this would also involve the inclusion of more parameters in the model (up to hundreds of parameters; see Oliveros-Ramos et al., 2017), which are only poorly constrained. Therefore, while explicitly including fish in a model widens the possibilities for controlling the system, it may also increase the sources of uncertainty. Here we utilised an already-validated physical and biogeochemical model and parameterised the loss of zooplankton due to fluctuations in small pelagic fish, without adding additional complexity to the model. Our results may be a baseline reference for further studies exploring such an effect.

Appendix A: Plankton parameters

Our reference simulation has the same configuration as in Jose et al. (2017) which in turn is based on the parameters used in Gutknecht et al. (2013a), with minor adjustments. Table A1 provides a list of the most relevant parameters for this study, as well as their descriptions and units. This is not a comprehensive list; for the full list of parameters and their values please see Gutknecht et al. (2013a) and Jose et al. (2017).

Table A1. Plankton parameters in the model. The complete list of biogeochemical parameters is given in Gutknecht et al. (2013a), and the values for the reference simulation are provided in Jose et al. (2017).

Symbol	Description	Value	Unit
αP_S	Initial slope of P–I curve for P_S	0.025	$(\text{W m}^{-2})^{-1} \text{d}^{-1}$
αP_L	Initial slope of P–I curve for P_L	0.04	$(\text{W m}^{-2})^{-1} \text{d}^{-1}$
μ_{P_S}	Mortality rate of P_S	0.027	d^{-1}
μ_{P_L}	Mortality rate of P_L	0.03	d^{-1}
$K_{\text{NH}_4 P_S}$	Half-saturation constant for uptake of NH_4 by P_S	0.5	mmol N m^{-3}
$K_{\text{NH}_4 P_L}$	Half-saturation constant for uptake of NH_4 by P_L	0.7	mmol N m^{-3}
$K_{\text{NO}_3 P_S}$	Half-saturation constant for uptake of $\text{NO}_3 + \text{NO}_2$ by P_S	1.0	mmol N m^{-3}
$K_{\text{NO}_3 P_L}$	Half-saturation constant for uptake of $\text{NO}_3 + \text{NO}_2$ by P_L	2	mmol N m^{-3}
w_{P_L}	Sedimentation velocity of P_L	0.5	m d^{-1}
$f_{I_{Z_S}}$	Assimilation efficiency of Z_S	0.75	–
$f_{I_{Z_L}}$	Assimilation efficiency of Z_L	0.7	–
$g_{\text{max}_{Z_S}}$	Maximum grazing rate of Z_S	0.9	d^{-1}
$g_{\text{max}_{Z_L}}$	Maximum grazing rate of Z_L	1.2	d^{-1}
$e_{Z_S P_S}$	Preference of Z_S for P_S	0.75	–
$e_{Z_S P_L}$	Preference of Z_S for P_L	0.25	–
$e_{Z_L P_S}$	Preference of Z_L for P_S	0.26	–
$e_{Z_L P_L}$	Preference of Z_L for P_L	0.5	–
$e_{Z_L Z_S}$	Preference of Z_L for Z_S	0.24	–
k_{Z_S}	Half-saturation constant for ingestion by Z_S	1	mmol N m^{-3}
k_{Z_L}	Half-saturation constant for ingestion by Z_L	2	mmol N m^{-3}
μ_{Z_S}	Mortality rate of Z_S	0.025	$(\text{mmol N m}^{-3})^{-1} \text{d}^{-1}$
μ_{Z_L}	Mortality rate of Z_L	0.05	$(\text{mmol N m}^{-3})^{-1} \text{d}^{-1}$
γ_{Z_S}	Metabolic rate of Z_S	0.05	d^{-1}
γ_{Z_L}	Metabolic rate of Z_L	0.05	d^{-1}

Appendix B: Mesozooplankton evaluation

Modelled large zooplankton is higher than observed night-time mesozooplankton above 100 m (Fig. B1). Deep-water zooplankton is absent in the model, while observed mesozooplankton is present at depths between 600 and 1000 m. Mesozooplankton below 200 m further increases during the daytime (data not shown; please see Fig. 4 in Kiko and Hauss, 2019).

Figure B1. Same as Fig. 2, but (a–e) show a depth range up to 1000 m and a logarithmic horizontal axis.

Appendix C: Temporal variability

The NHCS presents high climatological and interannual variability. In our modelled region, small phytoplankton concentrations are relatively stable throughout the year. On the other hand, large phytoplankton production exhibits a clear seasonal pattern, with the largest concentrations presented in austral summer (Fig. C1). Echevin et al. (2008) discuss a similar seasonal pattern found in their model. Such a pattern has also been identified in satellite-derived primary production (Messié and Chavez, 2015).

Figure C1. Primary production by large and small phytoplankton during the last climatological year of the simulation, averaged over the upwelling region (see Fig. 1) and integrated over the upper 100 m in the reference scenario.

Appendix D: Plankton surface concentrations

Experiments A and B exhibit very similar spatial trends. Figure D1 provides an overview of surface plankton concentrations in their reference scenario and their changes in the experiments. Note that in the two sets of experiments, large zooplankton increased when mortality decreased and vice versa. On the other hand, small zooplankton presents a counter-intuitive response when mortality decreases, responding to the change in the concentration of its predator rather than to changes in mortality, and an ambiguous response in the high mortality cases. Large and small phytoplankton exhibit opposite trends, seemingly driven by the concentration change of their main predator (large and small zooplankton, respectively).

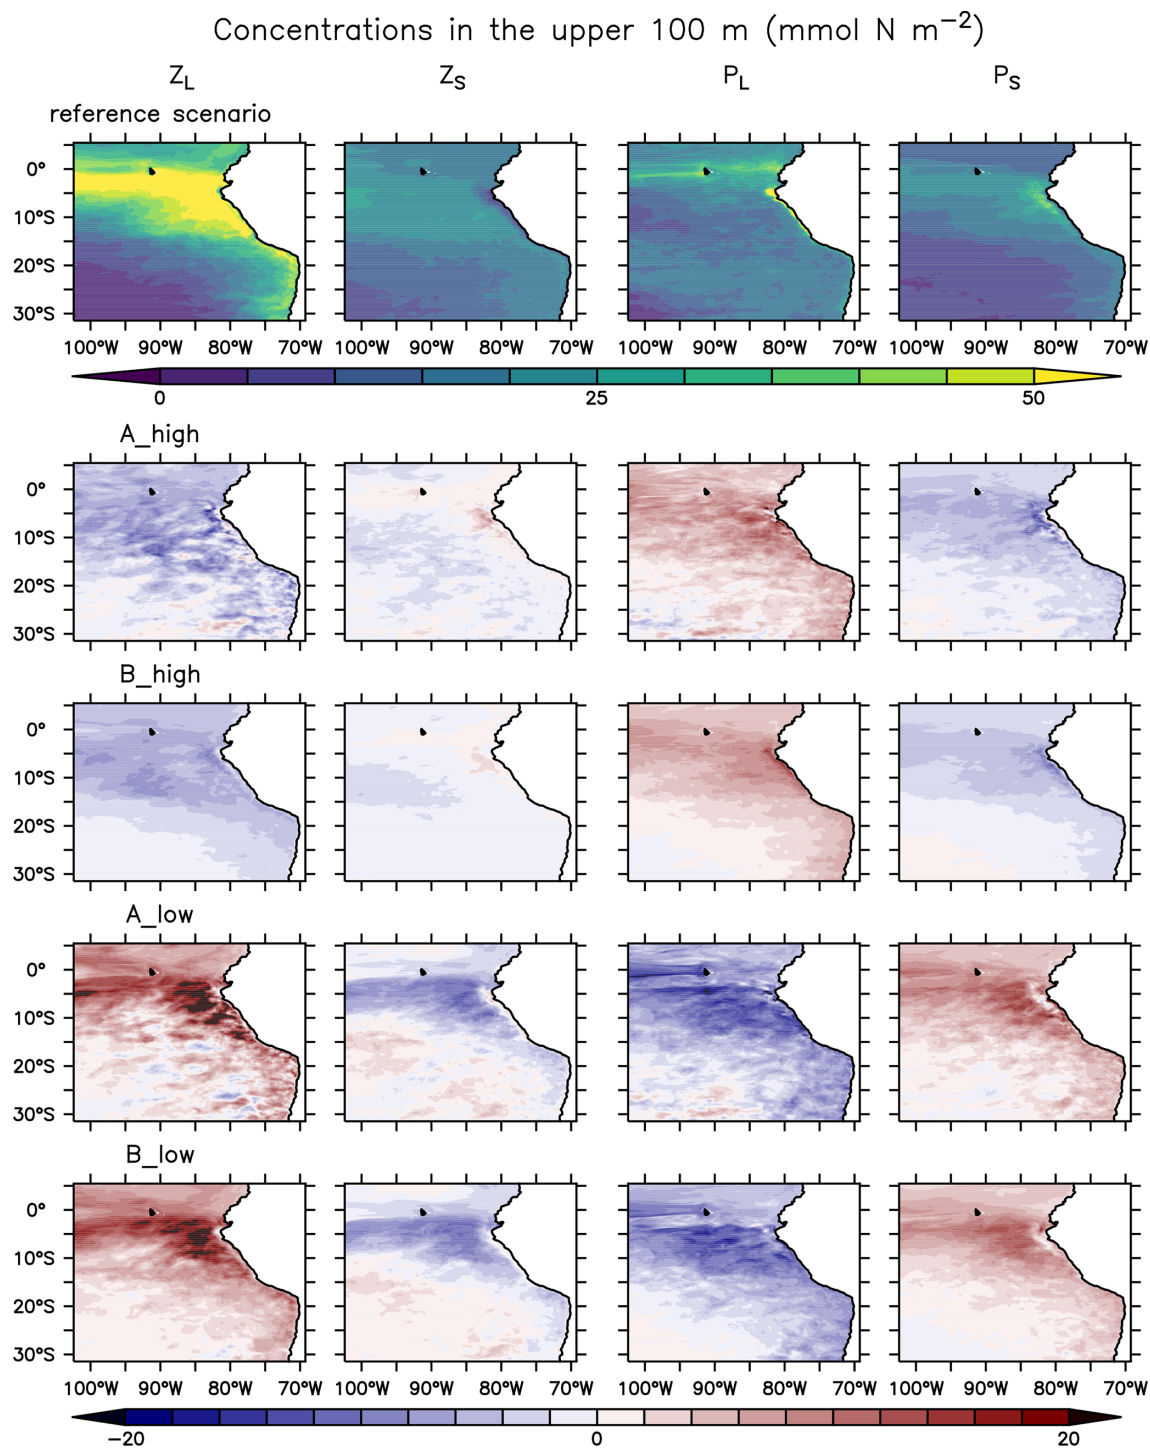

Figure D1. Large and small zooplankton (Z_S and Z_L) and large and small phytoplankton (P_L and P_S) integrated over the upper 100 m of the water column (mmol N m^{-2}). Rows from top to bottom: reference scenario and difference between experiments A_high, B_high, A_low and B_low and the reference scenario.

Code and data availability. Code and data used in this study are available upon request. The ROMS model is maintained at <https://www.myroms.org> (last access: 22 April 2021).

Supplement. The supplement related to this article is available online at: <https://doi.org/10.5194/bg-18-2891-2021-supplement>.

Author contributions. IK and AO designed the study. YSJ carried out the simulations. MHC performed the analysis. RK and HH provided zooplankton observations and expertise on zooplankton dynamics in the NHCS. All authors discussed the results and wrote the manuscript.

Competing interests. The authors declare that they have no conflict of interest.

Acknowledgements. We would like to thank Tianfei Xue for carrying out some of the model simulations. We also thank the three anonymous reviewers for their very helpful and constructive comments. Simulations were performed using the computing facilities of the Norddeutscher Verbund zur Förderung des Hoch- und Höchstleistungsrechnens – HLRN.

Financial support. This research has been supported by the Bundesministerium für Bildung und Forschung projects CUSCO and Humboldt Tipping (grant no. 03F0813A and grant no. 01LC1823B). Rainer Kiko was further supported via a Make Our Planet Great Again grant of the French National Research Agency within the Programme d'Investissements d'Avenir, reference ANR-19-MPGA-0012. Further support for this project was provided by the Deutsche Forschungsgemeinschaft (DFG), under the Sonderforschungsbereich 754 "Climate-Biogeochemistry Interactions in the Tropical Ocean" project (<http://www.sfb754.de>, last access: 3 May 2021).

The article processing charges for this open-access publication were covered by a Research Centre of the Helmholtz Association.

Review statement. This paper was edited by Stefano Ciavatta and reviewed by three anonymous referees.
