### 28 Abstract

29 Annual plankton succession has been investigated for many decades and hypotheses ranging from

30 abiotic to biotic mechanisms have been proposed to explain this recurrent pattern. Here, using data

- 31 collected by the Continuous Plankton Recorder (CPR) survey and models originating from the
- 32 MacroEcological Theory on the Arrangement of Life (METAL), we investigate annual
- 33 phytoplankton succession in the North Sea at a species level. Our results show that this
- 34 phenomenon can be well predicted by models combining photosynthetically active radiation, 35 temperature and macro-nutrients. Our findings suggest that annual phytoplankton succession, at
- 36 community level, originates from the interaction between species ecological niche and annual
- 37 environmental fluctuations. We discuss our results in the context of traditional hypotheses
- 38 formulated to explain this recurrent pattern in the marine field, including those on the initiation,
- 39 the development and the termination of a typical extratropical spring bloom.
- 40

- 43 Plankton Recorder (CPR), METAL theory.

#### 45 1. INTRODUCTION

46

47 Annual Plankton Succession (APS) is defined as the recurrent pattern of species abundance 48 observed during the annual cycle (Cushing 1959, Winder and Cloern 2010, Sommer et al. 2012, 49 Romagnan et al. 2015). In temperate and polar biomes, phytoplankton abundance varies from 50 periods of proliferation in spring and autumn to periods of decline in summer and winter. In 51 subtropical and tropical waters, where seasonal changes in solar radiation and temperature are less 52 prominent, plankton abundance is more stable at an annual scale (Dakos et al. 2009). In the 53 Mediterranean Sea, eukaryotic primary producers appear from early spring with the following 54 sequence: pico-eukaryotes, silicoflagellates, diatoms and dinoflagellates (Romagnan et al. 2015).

55 APS has been widely described in marine ecosystems, leading to a variety of potential 56 explanations often based on mechanisms such as bottom-up to top-down controls (Sverdrup 1953, 57 Margalef 1978, Sommer et al. 1986, Behrenfeld 2010, Sommer et al. 2012, Smyth et al. 2014, 58 Romagnan et al. 2015, Atkinson et al. 2018). Gilbert et al. (2012), Romagnan et al. (2015) and 59 Barton et al. (2015) have provided evidence for a strong influence of the physical environment on 60 phytoplankton dynamics, suggesting a bottom-up control of annual succession. A substantial 61 impact of species interaction (i.e. grazing) imposing a top-down control (e.g. mesozooplankton 62 species on protists) has also been suggested in the western part of the English Channel, however 63 (Kenitz et al. 2017, Fileman et al. 2010).

64 The seasonal cycles of irradiance, temperature and stratification and the associated changes 65 in pycnocline, thermocline and halocline are known to be closely associated with the onset of phytoplankton growth (Longhurst 1998), and nutrients influence the extent of the phytoplankton 66 67 bloom (Sommer et al. 2012). Although APS starts typically by the onset of the spring bloom in 68 most extra-tropical regions, winter is a key period preparing the ingredients needed to trigger the start of phytoplankton proliferation (Sommer et al. 2012). During winter, oceans and seas lose heat 69 70 from their surface waters, which become denser and consequently start to sink (Mann and Lazier 71 1996). Wind intensifies oceanic turbulence, which in turn brings nutrients (nitrate, phosphate and 72 silicic acid) in the euphotic zone (Falkowski and Oliver 2007) while diluting phytoplankton in the 73 water column (Behrenfeld 2010).

74 According to the Sverdrup's model (Sverdrup 1953), the spring phytoplankton bloom can 75 develop when the Mixed Layer Depth (MLD), which can reach several hundred meters in the 76 North Atlantic Ocean during winter (Reygondeau and Beaugrand 2010), is shallower than a critical 77 depth at which the integral of net growth rate becomes zero over the water column. Sverdrup's 78 theory has greatly stimulated research and this hypothesis is applicable to both deep waters and 79 off-shore environments but not in shallow coastal systems (Behrenfeld 2010, Sathyendranah et al. 80 2015, Lévy 2015). The intensity of the phytoplankton bloom is strengthened when solar heating 81 and reduced winds increase vertical stratification, leading to a strong thermocline. Irradiance is an 82 important factor due to its influence on critical depth and vernal stratification, allowing species to 83 remain in the euphotic zone. It has also been observed that the phytoplankton bloom sometimes 84 starts before water stratification, which has led some authors to challenge Sverdrup's concept 85 (Behrenfeld 2010). For instance, the dilution-recoupling hypothesis from Behrenfeld (2010) 86 explains how the spring phytoplankton bloom is the result of an increase in growth at a time of 87 strong dilution of grazers in the water column due to the absence of stratification. Progressive 88 stratification during the bloom reinforces the coupling between phytoplankton and grazers, and

the reduction in nutrients availability - combined to a high grazing pressure - induces bloom termination. When the mixed layer deepens and increases macro-nutrients concentration in the euphotic zone, an autumn phytoplankton bloom can occur (Longhurst 1998); it ends rapidly, however, because of light limitation (Sverdrup 1953, Geider et al. 2014).

93 The main objective of this study is to reconstruct APS using models of increasing complexity 94 generated from the Macro-Ecological Theory on the Arrangement of Life (METAL; Beaugrand 2015) that consider a set of environmental parameters known to influence marine phytoplankton 95 dynamics such as temperature, photosynthetically active radiation and macro-nutrients. METAL 96 97 unifies together behavioural, physiological, phenological, biogeographic and long-term 98 community shifts and consequently allows one to predict how communities form and how they are 99 altered by environmental fluctuations, including climatic variability and global climate change 100 (Beaugrand et al. 2010, 2013a, 2014, 2018). The strength of this approach is to consider that, even 101 though ecosystems are complex adaptive systems, basic organisation and sensitivity of communities can be predicted from simple founding principles. A significant proportion of the 102 103 spatial and temporal adjustments of marine communities are deterministic, being thereby 104 intelligible, which opens the way to testable predictions. In this study, our objectives are to test 105 whether APS is related to the interaction between the ecological niche (sensu Hutchinson 1957) 106 of species and seasonal fluctuations in their environment, and to identify the key ecological 107 dimensions of the niche that control the annual phytoplankton dynamics.

108 Here, using data from the Continuous Plankton Recorder (CPR) survey (Reid et al. 2003), 109 we first characterise APS in the North Sea. We model this phenomenon using METAL and 110 compare observed and predicted patterns. We then investigate how natural environmental fluctuations drive phytoplankton seasonality from initiation to termination. Finally, we discuss our 111 112 results in the context of APS (Widdicombe et al. 2010, Sommer et al. 2012, Romagnan et al. 2015), 113 including hypotheses that have been proposed to explain the spring bloom such as the critical depth 114 and turbulence hypotheses (Sverdrup 1953, Huisman et al. 1999), dilution-recoupling hypothesis 115 (Behrenfeld 2010), and net heat flux hypothesis (Smyth et al. 2014).

116

# 117 2. MATERIALS AND METHODS

### 118 2.1. Biological data

119 Biological data originated from the Continuous Plankton Recorder (CPR. 120 https://www.cprsurvey.org/data/our-data/) survey. This marine biological monitoring programme, 121 currently operated by the Marine Biological Association (MBA), has sampled the North Atlantic Ocean and its adjacent seas on a routine monthly basis since 1946 at a depth of approximately 7-122 123 10 meters (Reid et al. 2003). Data from this programme have been extensively used to (i) 124 investigate APS (e.g., Colebrook 1979, 1982c, Zhai et al. 2013, Barton et al. 2015), (ii) characterise 125 pelagic biodiversity (e.g., Beaugrand et al. 2002, Barnard et al. 2004), (iii) document distributional, 126 phenological and physiological responses of marine species to climate change (e.g., Helaouët and 127 Beaugrand 2009, Beaugrand et al. 2009, Thackeray et al. 2016, Beaugrand and Kirby, 2018) and 128 (iv) anticipate the consequences of global warming in the pelagic realm (e.g., Reid et al. 1998, 129 Beaugrand et al. 2015).

In this study, we restricted our analyses to phytoplankton communities in the North Sea (1°E - 4°E and 54°N - 56°N; Fig. S1) and considered 90 species or taxa commonly monitored by the CPR survey over the period 1946-2016 (Table S1). The area was chosen because it was regularly sampled over the last decades and is located relatively far from the coastline. In the selected area and for all selected taxa, we calculated a climatology for each Julian day (i.e. 365) by averaging the selected taxa abundances over the period 1958-2016.

## 136 **2.2. Environmental data**

137 Nutrients data originated from the World Ocean Atlas 2013 V2, provided by NOAA 138 National Centers for Environmental Information (NCEI), Silver Spring, Maryland, USA 139 (https://www.nodc.noaa.gov/OC5/woa13/woa13data.html) (Locarnini et al. 2013). It is a 140 scientifically quality-controlled database of selected historical in situ surface and subsurface oceanographic measurements for phosphate ( $\mu$ mol. L<sup>-1</sup>), silicate ( $\mu$ mol. L<sup>-1</sup>) and nitrate ( $\mu$ mol. L<sup>-1</sup>) 141 <sup>1</sup>). Monthly means are provided for these three parameters, on a 3D grid of  $1^{\circ}$  latitudes by  $1^{\circ}$ 142 143 longitude by 37 depth levels. Here, we calculated the average nutrients concentration in the North Sea (1°E - 4°E and 54°N - 56°N; Fig. S1) for the first 20m. From this dataset, we calculated the 144 145 N/P ratio (Redfield 1958), which is known to modulate APS (Falkowski et al. 2000).

We used the Photosynthetically Active Radiation (PAR; Einstein . m<sup>-2</sup>. day<sup>-1</sup>), solar radiation 146 147 spectrum in the wavelength range of 400-700 nm, as a proxy of the level of energy that can be 148 assimilated by photosynthetic organisms (Asrar, Myneni & Kanemasu, 1989). PAR regulates both 149 the composition and evolution of marine ecosystems, influencing the growth of phytoplankton and 150 in turn the development of zooplankton and fish. Data were provided by the Giovanni online data 151 system, developed and maintained by the NASA GES DISC (http://gdata1.sci.gsfc.nasa.gov/daac-152 bin/G3/gui.cgi?instance\_id=ocean\_month). A monthly climatology of PAR at a spatial resolution 153 of 9 km was carried out by compiling data of the Sea-viewing Wide Field-of-view Sensor 154 (SeaWiFS) from 2009 to 2012.

155 Because of the well-known influence of temperature (Beaugrand et al. 2018), we assessed 156 the thermal environment of the 90 phytoplankton species over our region of interest using Sea 157 Surface Temperature (SST) from the Optimum Interpolation (OI), which is based on both in situ 158 and satellite observations (see Reynolds et al. 2002 for a full description of the OI analysis). In 159 contrast to other environmental data which were only available at a monthly resolution, we used 160 daily SST for a finer estimation of the thermal preferendum of species. We first calculated daily SSTs on a 1° by 1° grid from January 1982 to December 2017 and data were then averaged in the 161 area ranging from 1°E to 4°E and from 54°N to 56°N (Fig. S1). Annual changes in the 162 163 environmental parameters are shown in Fig. 1.

# 164 **2.3.** Examination of APS from the CPR survey

First, we removed species that had average annual abundance < 0.5 in the target area (Table S1, Fig. S1). This procedure led to the selection of 81 phytoplankton species (Table S1) for which we estimated average daily abundances over the region of interest for the period 1946-2015. To minimise short-term fluctuations and reduce the noise inherent to these data, we applied an order-6 symmetrical moving average on each daily time series (Legendre and Legendre 1998).

170 A standardised Principal Component Analysis (PCA; Jolliffe 1986) was applied on the 171 correlation matrix 81 phytoplankton species x 365 days and the first three principal components (PCs) were examined to identify changes in annual succession. Species were then sorted according
to their phenology by using normalised eigenvectors, i.e. linear correlation values with the
corresponding PCs higher than |0.5| (Table S1). Only significative axes (PCs) were represented

175 (Fig. 2).

Finally, we clustered phytoplankton species into five groups: Bacillariophyceae,Dinophyceae, Primnesiophyceae, Dictyochophyceae and Cyanophyceae.

#### 178 **2.4. Generation of pseudo-species using models from the METAL theory**

We modeled patterns of APS using METAL (Beaugrand et al. 2014, 2018). First, we generated a pool of uni-dimensional niches (i.e., niches with only one ecological dimension) by using a Gaussian model (Ter Braak 1996):

182 
$$A = c e^{-\left(\frac{(x-x_{opt})^2}{2t^2}\right)}$$
 (1)

where A is the abundance of a species as a function of the value of a given environmental parameter x; c is the maximum abundance of a pseudo-species with c being fixed to 1 (Beaugrand, 2015);  $x_{opt}$  is the environmental optimum (e.g. the best environmental condition for a given species that can reach the highest level of abundance) and t is the ecological amplitude of a pseudo-species (i.e. the environmental range where a species can occur) for a given environmental factor (Table S3). Species abundance along environmental gradients is generally modelled using a Gaussian model (Gauch et al. 1974).

Multi-dimensional niches (i.e., niches with 2 or more ecological dimensions) were modelledas follows:

192 
$$A = Ce^{-\frac{1}{2}} \left[ \left( \frac{x_1 - x_{opt1}}{t_1} \right)^2 + \dots + \left( \frac{x_n - x_{optn}}{t_n} \right)^2 \right]$$
(2)

193 with  $2 \le n \le 5$  ecological dimensions,  $x_1$  to  $x_n$  the values of the environmental parameters, 194  $x_{opt1}$  to  $x_{optn}$ , the optimum values of  $x_1$  to  $x_n$ , and  $t_1$  to  $t_n$ , the ecological amplitudes of  $x_1$  to  $x_n$ .

195 Our simulations were based upon six environmental parameters: (i) SST, (ii) PAR, (iii) 196 nitrate, (iv) phosphate, (v) silicate, and (vi) N/P ratio. When the N/P ratio was considered, neither 197 nitrate nor phosphate concentrations were included in the models to avoid possible bias related to 198 multicollinearity. We performed simulations using all possible environmental combinations from 199 one to five ecological dimensions (Table S2), leading to a total of 84 runs (i.e. simulations): 16 200 uni-dimensional runs, 23 two-dimensional runs, 29 three-dimensional runs, 13 four-dimensional 201 runs and 3 five-dimensional runs (Table S2). The characteristics (optimum and ecological 202 amplitude) of all niches are presented in Table S3. For example, for temperature, we defined 7 203 optimum values (i.e. values corresponding to the highest abundance for a given pseudo-species) 204 ranging from 0 to 36°C by increment of 6°C and 4 ecological amplitudes from 1 to 10°C by 205 increment of 3°C, leading to the creation of 28 (4 x 7) virtual (or pseudo-) niches.

For each run, a large number of niches (from 21 to 15,431,472) was created (Table S3). To determine the total number of niches per run, we multiplied the number of niches generated for a given dimension by the number generated for all other ecological dimensions. For example, for a run based on temperature, PAR and nitrate (i.e. a three-dimensional run), the total number of niches was  $28 \times 21 \times 27 = 15,876$  ecological niches (with 28 niches for SST, 21 for PARc and 27 for nitrate; Table S3).

212 To test whether the resolution of niches (i.e. the number of points along the niches) affected 213 our analyses, we compared two extreme cases of uni-dimensional models (i.e. low and high 214 resolutions) using each ecological variable. We added the term "bis" after the name of the variable 215 to identify high-resolution niche (Tables S3-S4). When the word 'bis' was absent, the uni-216 dimensional niche had a low resolution. Because of the high number of categories generated in 217 the high-resolution case (e.g. 144,648,000 categories for a run based on temperature bis, PARa bis 218 and phosphate bis), we did not perform high-resolution analyses based on more than one 219 dimension because of calculation time estimated to be ~4 months on a high-performance computer 220 of 88 cores.

To examine the sensitivity of our analyses to low PAR values, we considered three minimum values: 1 (termed "PARa", Table S3), 10 ("PARb") and 20 ("PARc") E.m<sup>-2</sup>.day<sup>-1</sup>.

Finally, annual estimations of pseudo-species abundances were assessed by performing a cubic interpolation of the 1-5D niches with the corresponding environmental variables. Four runs on APS are closely examined as examples: (i-iii) three uni-dimensional runs based on either (i) SST, (ii) PAR or (iii) nitrate (Fig. 3) and (iv) one three-dimensional run based on SST, PAR and nitrate (Fig. 4).

### 228 **2.5.** Comparisons of predicted and observed seasonal patterns

Comparisons between predicted and observed annual patterns in phytoplankton abundance were performed in two ways. First, we calculated the coefficient of linear correlation (Pearson's correlation coefficient; Fig. 5 and Fig. S3). Second, we used the Mean Absolute Error (MAE; Fig. S3) that measures the average magnitude of the errors in a set of predictions, without considering their direction.

234

$$MAE = \sum_{i=1}^{n} \frac{|Xi-Yi|}{r} \tag{3}$$

with n the number of differences to be tested,  $X_i$  is prediction *i* and  $Y_i$  is observation *i*. Equation (3) represents the absolute differences between predictions and observations, divided by the number of differences to be tested (with all individual differences having equal weight). It is a negatively-oriented score, which means that the lower values are related to the strongest correlations.

240 Pearson's correlation coefficients and MAEs were calculated for each run between all 241 observed and predicted daily patterns in (pseudo-) species abundance, leading to a correlation or 242 MAE matrix  $u \times v$  (species x pseudo-species). We then identified the highest positive correlations 243 and the lowest MAE values. For each run, we therefore obtained two vectors using the average 244 correlation and MAE values calculated for each species (Fig. S4). The daily normalised (between 245 0 and 1) pseudo-species abundances that showed the highest correlation with observed species 246 were plotted against daily observed species abundances to graphically depict the relationships (Fig. 247 5).

We then tested both correlations and MAEs using null models that considered (or not) temporal autocorrelation. First, we randomly generated a number of daily time series

corresponding to the total number of pseudo-species generated for each run. Although the number 250 251 of time series was small for 1D runs, it became important when the number of dimensions 252 increased as we multiplied the number of niches per parameter. The procedure was repeated 1000 253 times and, for each simulation, the average correlation and MAE values were calculated. To 254 consider temporal autocorrelation, we generated two million of time series and kept the first 1000 255 with a 30-order (i.e., 30 days/~one-month autocorrelation for daily time series) autocorrelation 256 higher than average 30-order autocorrelation found in observed daily time series. We represented 257 the results in a diagram that exhibited the observed average correlation for each run and the 1000 258 correlations found using the null model with (red) and without (blue) autocorrelation (Fig. S3). 259 For each combination of environmental variables (i.e. 84 runs), we calculated the probability of significance of each correlation (Table S4). Finally, we used contour diagrams to identify (i) the 260 261 most important environmental parameters and (ii) the number of dimensions to accurately 262 reconstruct APS. This graphical examination allowed us to highlight the number of species that 263 exhibits the highest correlations in each run (Fig. 6). 264

## 265 **3. RESULTS**

### 266 **3.1. Seasonal changes in environmental parameters in the North Sea**

Temperature exhibited a minimum at the beginning of March and a maximum at the end of July-August (Fig. 1). PAR showed minimum and maximum values in December-January and June, respectively. The highest concentrations in nitrate, phosphate and silicate were observed in winter and reached their lowest concentrations from the end of spring to the end of summer. Except for SST, no variation was captured within a given month because monthly means were used for all other parameters.

### 273 **3.2. Observed annual phytoplankton succession**

274 We examined APS based on CPR plankton data by means of a PCA (Fig. 2). The use of the 275 first three principal components allowed us to differentiate five periods, each being characterised 276 by a species assemblage: (i) an early-spring stage (Fig. 2b left part of the panel, 8 species negatively correlated to PC1), (ii) a spring stage (Fig. 2c, 22 species positively correlated to PC2), 277 278 (iii) a widespread summer stage (Fig. 2a, 28 species positively related to PC1), (iv) a late 279 summer/beginning of autumn stage (Fig. 2d, 13 species negatively correlated to PC3) and (v) an 280 autumn stage (Fig. 2b right part of the panel, 8 species negatively correlated to PC1). The summer stage (Fig. 2a) was characterised by the highest species richness, but showed a low proportion of 281 282 diatoms in comparison to both spring or autumn stages; silicoflagellates were also present (Table 283 S1). Other principal components were not represented because they did not bring additional 284 information.

### 285 **3.3. Modelled annual phytoplankton succession**

We reconstructed APS by using models of growing complexity (i.e., by considering a growing number of niche dimensions) including all combinations of SST, PAR, nitrate, phosphate, silicate and N/P ratio (a total of 84 runs). Here, we focused on four examples of modelled APS reconstructed by using different ecological dimensions (Fig. 3 and 4). The first run, based on SST only, showed two main phases of high phytoplankton abundance (also representative of a high species richness) in summer (Fig. 3a) and winter (Fig. 3b) and two minor phases in spring (Fig. 292 3c) and autumn (Fig. 3c). The winter phase of high abundance did not correspond to any observed

- patterns (Fig. 2 *versus* Fig. 3). The second run, based on PAR only, showed several peaks of high
- phytoplankton abundance in spring, summer and autumn (Fig. 3d-f). These patterns were close to
- observed patterns of annual succession (Fig. 2), suggesting an important role of PAR in the
- 296 modulation of APS. The third model, based on nitrate only (Fig. 3g-i), showed an important winter
- 297 peak in phytoplankton abundance, not detected in the observations (Fig. 2 *versus* 3). This result 298 suggests that considering nitrate only was not sufficient to reconstruct APS. The fourth model, that
- combined SST, PAR and nitrate (Fig. 4a-e), was more efficient to reproduce APS observed in the
- 300 CPR data, especially the late-summer phase (Fig. 4 *versus* Fig. 2). A closer examination of the
- 301 relationships between predicted and observed APS is performed below.

# 302 **3.4. Relationships between observed and modelled annual phytoplankton succession**

# 303 **3.4.1. Reconstruction of species seasonal patterns**

304 We calculated the Pearson's correlation coefficients between observed and simulated 305 (pseudo-) species for all 84 runs; we remind here that our runs were characterised by a growing 306 number of ecological dimensions - ranging from one to five - and that all combinations (C=84) of 307 environmental parameters were tested. We chose the best correlations and examined graphically 308 the relationships between observed and predicted phytoplankton abundances (Fig. 5). Figure 5 309 shows all the relationships between phytoplankton species considered in the analyses and pseudospecies created from METAL. For all phytoplankton groups, simulated pseudo-species reproduced 310 311 observed seasonal patterns well: most annual phytoplankton patterns in observed and simulated 312 phytoplankton species were closely related (e.g., Skeletonema costatum and Thalassiosira spp.) 313 with the exception of Paralia sulcata and Dactyliosolen antarcticus (Fig. 5). Correlation and MAE 314 values are examined in detail in the following sections.

# 315 **3.4.2. Identification of key ecological dimensions to reconstruct APS**

316 To identify key ecological dimensions, we calculated the average of the best correlations and 317 MAEs between observed and simulated (pseudo-) species for all 84 runs (Table S4, Fig. S3). We 318 tested our correlations and MAEs using a null model with and without consideration for temporal 319 autocorrelation. While some MAE values were significant for some 1D runs (Fig.S3), APS was 320 better reproduced when at least three dimensions were considered (Fig. S3). Not all correlations 321 were significant for models based on three or more ecological dimensions while considering five dimensions did not improve the percentage of explained variance (i.e. model quality). This 322 323 suggests that the selection of relevant environmental variables is more important than considering 324 a too high number of ecological dimensions.

# 325 **3.4.3. Identification of key environmental variables to reconstruct APS**

326 We then identified the most relevant environmental parameters and the number of ecological 327 dimensions that best reproduce APS (Fig. 6). We remind here that APS is the result of species 328 phenology (i.e., species seasonal patterns). Uni-dimensional models (1D, Runs 1-16) explained 329 poorly observed seasonal changes in species abundance, with the exception of Run 2 that was 330 exclusively based on SST (Fig. 6a); for Run 2, eight species showed their highest correlations 331 between observed and modelled seasonal patterns. Bi-dimensional models (Runs 17-39) also 332 explained poorly species seasonal patterns and only 3 species exhibited their highest correlations 333 when the model was based on both temperature and PAR (Fig. 6a, Table S2). Better results were achieved when models were based on three or more ecological dimensions. Three-dimensional
models (Runs 40-68) had 29 highest correlations between observed and modelled seasonal patterns
(Fig. 6a). Run 51 based on SST, N/P and PARc (i.e., a minimum value of PAR=20 E.m<sup>-2</sup>.day<sup>-1</sup>)
exhibited 10 highest correlations. Four-dimensional (Runs 69-81) and five-dimensional models
(Runs 82-84) had 25 and 14 highest correlation values, respectively.

We also examined the correlations between each simulated and observed seasonal patterns for all species and runs (Fig. 6b). The figure showed that even if best results were achieved for models based on SST only (Run 2), results were similar when three or more dimensions were included. Low correlations generally appeared when the triplet SST/PAR/macro-nutrient was not used (Fig. 6b and Table S2, e.g., Runs 53-56), revealing that the combination of these variables was important to reproduce most species seasonal patterns.

345

### 346 4. DISCUSSION

### 347 4.1. Annual phytoplankton succession

348

349 The METAL theory suggests that large-scale patterns in biodiversity emerged from the 350 niche-environment interactions that propagate from the species to the community level (Beaugrand 351 et al. 2013b, Beaugrand et al. 2015, Beaugrand et al. 2018). Here, our results show that APS -352 including the spring bloom - may also originate from the niche-environment interaction (Fig. 5). 353 APS has been frequently investigated at the group level (e.g. plankton functional type, plankton 354 ecology groups or categories). However, our study shows that even within a given ecological or 355 taxonomic group, species reacts to environmental fluctuations individually through the nicheenvironment interaction, conforming themselves to the principle of species individuality 356 (Whittaker 1975) (Fig. 5). Our study therefore suggests that it is important to investigate APS by 357 358 exploring ecological patterns and processes at a species level.

359 Our results show a prominent control of APS by environmental conditions in the North Sea. 360 Studying APS in the Mediterranean Sea, Romagnan et al. (2015) have also provided evidence for a strong control of the physical environment on APS. Even though our modelling approach 361 362 reproduced well the seasonal cycle of eight species when based on SST only, better results were achieved when three or more ecological dimensions were considered (Fig. 6). Considering five 363 364 dimensions did not improve substantially the percentage of explained variance, probably because seasonal changes in nitrate, phosphate and silicate concentrations are highly correlated in the North 365 366 Sea.

367 Our investigation of APS revealed four main microphytoplanktonic succession in the North 368 Sea (see Table S1 for a list of the species considered in our study). The first assemblage is 369 composed of species that exhibited their highest abundance at the beginning of spring and a second 370 less important peak in autumn (PC1 in Fig. 2b, Fig. 5). This microphytoplanktonic assemblage, 371 generally composed of large diatoms (Table S1 and Fig. 5, e.g. Thalassionema nitzschioides, 372 Ditylum brightwellii), was primarily controlled by PAR and nutrients availability in our models. 373 PAR is an essential parameter limiting photosynthesis and its influence on growth rate is well 374 known (Eppley & Sloan, 1966). PAR is a strong limiting factor in areas above the polar circle 375 (McMinn & Martin, 2013) but also in lower latitude regions such as the North Sea (Peeters et al.

376 1993). Nutrients positively influenced growth rate and primary production (Goldman 1980, 377 Longhurst 1998). The first assemblage is also psychrophilic, reaching its highest abundance when 378 temperature is lowest and their lowest abundance when temperature is highest (Fig. 1). The 379 assemblage is not detected when PAR is highest and when PAR or nutrients concentration is lowest 380 (Fig. 1). Although not considered in our analyses, turbulence, mixing and high SST variability that 381 characterise early spring and autumn may also positively influence the occurrence of this 382 assemblage, which is more adapted to such an environment than dinoflagellates (Beaugrand et al. 383 2010, Holligan et al. 1980, Margalef 1978). In winter, PAR (or the number of daily light hours) 384 and to a lesser extent temperature limit diatom growth and deep-water column mixing combined to an absence of biological production enable nutrients to increase at the sea surface. 385

The second assemblage (e.g. *Chaetoceros* spp., *Coscinodiscus concinnus*) occurs generally between April and June at a time when silicate and to a lesser extent nitrate and phosphate concentrations diminish and temperature and PAR increase (Fig. 1, 2c and 5). This assemblage is less psychrophile than the first one and occur at a time when both temperature and PAR increase (Fig. 1).

391 The third assemblage is composed of species, mainly dinoflagellates (e.g. Ceratium fusus 392 and C. furca) and some small diatoms (e.g. Guinardia striata, G. flaccida), occurring when 393 temperature and PAR are high and conditions are oligotrophic (Fig. 1, 2a and 5). Silicate depletion 394 played an important role in the change of dominance observed between the second and the third 395 assemblage. In a mesocosm experiment, silicate deficiency was assumed to be the cause of the 396 strong reduction in large spring bloom diatoms and the replacement by flagellates (Jacobsen et al. 397 1995). Small diatoms need less silicic acid for the their skeleton and have a higher surface to 398 volume ratio which increases nutrient absorption (Miller, 2004). Dinoflagellates occur in areas and 399 at time when both temperatures are warm, SST variability low and the water column is well 400 stabilised (Beaugrand et al. 2010, Margalef 1978).

401 The fourth assemblage is composed of species (e.g. the diatom *Bellerochea malleus*, 402 *Biddulphia alternans*) having their occurrence from August to October (Fig. 2d and 5). Those 403 species occur when temperature is high and when nutrients concentration tends to increase. Those 404 warm-temperate species have their northern limit of spatial distribution in the North Sea (e.g. 405 *Bellerochea malleus*)(Barnard et al. 2004).

406 Despite the fact that four main microphytoplanktonic successions were identified by the PCA, many intermediate situations occur (Fig. 5). For example, some species (e.g. Rhizosolenia 407 setigera) exhibit a higher abundance when PAR are above 10 E.m<sup>-2</sup>.day<sup>-1</sup> but show a diminution 408 409 when temperature is high and conditions are oligotrophic (Fig. 5). A summer reduction is 410 sometimes not observed for species occurring between spring and autumn (e.g. Gyrosigma spp.). 411 Some species have a peak in late spring and another smaller one in autumn (e.g. Dactyliosolen 412 fragilissimus). Others have a small peak in spring and a high one in autumn (e.g. Leptocylindrus 413 danicus). Many species have narrow seasonal peaks not identified by the PCA (e.g. Asteromphalus 414 spp., Ceratium buceros, C. carriense). Because most observed patterns in annual abundance were 415 well reconstructed by our approach, it is likely that APS may result from the niche-environment 416 interaction (Fig. 5). Sharp or gradual environmental gradients interact with the niche of each 417 species within a multidimensional space to generate a variety of phenological patterns (Fig. 5).

The application of the Plankton Ecology Group (PEG) model in lakes and subsequently in 419 420 the marine realm (Sommer et al. 1986, Sommer et al. 2012) has suggested that (i) physics (light and stratification) controls the start and the end of the phytoplankton growth season, (ii) grazing 421 422 by metazoan plankton results in a clear water phase, (iii) nutrients define the carrying capacity of 423 phytoplankton, (iv) food limitation determines zooplankton abundances and (v) fish predation 424 determines zooplankton size structure. The PEG model has emphasised the role of physical factors, 425 grazing and nutrient limitation for phytoplankton. Our results have shown the key role of bottom-426 up processes in shaping APS and recall the importance of considering a combination of several 427 environmental factors, not only light. PAR and to a lesser extent SST, are important for the 428 initiation of the spring bloom, macronutrients for the end of the spring bloom and both SST and 429 macronutrients for the development of APS. Light (e.g. PAR, photoperiod), nutrients and 430 temperature are seen as master parameters controlling photosynthesis in physiological studies 431 (Geider et al. 1997, Longhurst 1998, McMinn & Martin 2013, Ras et al. 2013). While grazing may 432 have a substantial influence (Kivi et al. 1993, Fileman et al. 2010, Kenitz et al. 2017), the absence 433 of grazing consideration in our analyses did not prevent us to accurately reconstruct species 434 phenology (Fig. 5).

### 435 **4.2. The spring bloom**

436 Our study also provides evidence for a strong environmental control of the initiation, 437 development and termination phases of the spring bloom although processes are distinct from 438 those formulated by Gran and Braarud (Gran and Braarud 1935) and Sverdrup (1953). The Critical 439 Depth Theory (Sverdrup 1953) proposed that spring blooms in regions close to the North Atlantic 440 Drift Provinces develop when the Mixed Layer Depth (MLD) becomes shallower than the critical 441 depth (i.e., blooming can occur when MLD is less than the critical value), which was derived 442 analytically as a function of the amount of incoming radiation, water transparency and the energy 443 level at the compensation depth (i.e., the depth at which gross photosynthesis balances 444 phytoplankton respiration). According to the CDT, bloom initiation is only possible in spring in 445 high latitudes.

446 The possibility that the onset of the spring phytoplankton bloom occurs as a consequence of 447 decreased zooplankton grazing pressure has recently been proposed by Behrenfeld (2010). Our 448 models suggest that neither the occurrence of a MLD shallower than the critical depth nor a 449 dilution effect resulting from the occurrence of a deep MLD is necessary to reproduce bloom 450 initiation and more generally species phenology in the investigated North Sea region. The 451 integration of PAR - and to a lesser extent SST - in the models simply explained the initiation of 452 the spring bloom in the North Sea. Average light intensity in the mixed layer is well-known to 453 govern the timing of the spring bloom (Riley 1967; Legendre 1990), even if phytoplankton production losses due to mixing may also be important (Behrenfeld 2010). Some studies have also 454 reported that spring bloom may occur in the absence of water stratification (Townsend et al. 1992), 455 456 confirming that phytoplankton initiation may precede the establishment of a clear thermocline 457 (Colebrook 1979). Revisiting the dilution-recoupling hypothesis (Behrenfeld 2010), Beaugrand (2015) has also suggested PAR as a key driver of bloom initiation (his figure 5.27). Smyth and 458 459 colleagues (2014) have conveyed that the spring bloom started in the western part of the English 460 Channel (Station L4, Plymouth) when net heat flux becomes positive. Because net heat flux is highly positively related to irradiance and PAR (Beaugrand 2015), a strong control of PAR on the 461 462 initiation of the spring bloom may be expected.

463 Our models also suggest that the limitation in macro-nutrients is a key factor for bloom 464 termination, which is only in partial agreement with the Sverdrup and the Behrenfeld hypotheses. To model the end of the spring bloom, we did not have to include grazing (Sverdrup 1953) or a 465 466 coupling between grazers and phytoplankton (Behrenfeld 2010). Instead, the low macro-nutrients concentrations could explain alone bloom termination. As earlier, we do not state that grazing has 467 468 not an effect, but we suggest that the physical environment is an important driver. Large seasonal 469 changes in atmospheric forcing and ocean surface conditions shape, to a great degree, the seasonal 470 cycles of phytoplankton biomass, but also the relative abundance of phytoplankton species (Barton 471 et al. 2014). Beaugrand (2015) showed that phytoplankton and zooplankton seasonal fluctuations 472 were closely related in the North Atlantic region investigated by Behrenfeld (his figure 5.28), 473 suggesting a "bottom-up" control. More recently, Atkinson and colleagues (2018) demonstrated 474 that both the increase and termination of the spring bloom are encapsulated by zooplankton, 475 providing strong evidence against a top-down control.

476 Although the succession between diatoms and dinoflagellates can be well explained by 477 macro-nutrients and temperature in our models, it is well-known since Margalef (1979) that water 478 column stability is a key factor to explain the succession between these two functional groups. 479 Dinoflagellates are more sensitive than diatoms to turbulence (Karp-Boss et al. 2000). They can 480 realise significant vertical migration to nutrient rich area but cannot reproduce when turbulence is 481 too high (Estrada and Berdalet 1997). In contrast, diatoms can continue cell division and the 482 photosynthetic energy products are used to synthetize fatty acid that are converted to energy when 483 cells are exported below the euphotic zone; fatty acid can be considered as a buoyancy regulator 484 (Amato et al. 2017). It is possible that mixing and turbulence are not required in our models 485 because temperature is a proxy of mixing and turbulence conditions in the North Sea. Confirmation of our results should be searched in other regions experiencing different sequences of 486 487 environmental conditions.

### 488 **4.3. Uncertainties related to our approach**

The niche-environment interaction is certainly more unpredictable in the field than in our modelling approach for two main reasons. First, while the fundamental niche (*sensu* Hutchinson) was estimated here, the environment - through random meteorological conditions - may influence the realised niche of microalgae species. Second, phytoplankton community before and/or during the growth of a given species may alter species realised niche by competition for resources that lead to competitive exclusion. The trait-based approach of Breton et al. (2017) suggests that competitive exclusion prevails during *Phaeocystis* spp. bloom.

496 It is well-known that the underwater light available for photosynthesis (PAR) is a key 497 environmental variable for primary production (Cole and Cloern 1987, MacIntyre et al. 2000, 498 Foden et al. 2010, Capuzzo et al. 2013, 2015, 2018). Light field in the water column depends in 499 turn on phytoplankton biomass (self-shading), inorganic suspended particulate materials, colored 500 dissolved organic materials and water itself (IOCCG 2000). Recent works on light quality have 501 also revealed the important role of spectral irradiance on phytoplankton succession (Lawrenz and 502 Richardson 2017). In this study, we used surface PAR data that originated from a climatology. All 503 phytoplankton species can perform photo-regulation or photo-acclimation (i.e., the first occurs at 504 time scales of minutes and the second takes place in a few hours or a day) to limit photo-inhibition 505 in high light surface waters or optimise both light harvesting and Calvin cycle activity in the water 506 column (MacIntyre et al. 2000, Lavaud 2007, Dubinsky and Stambler 2009). In addition, photoacclimation processes can be conducted on different kinetic models and time scales (Cullen and
Lewis 1988), according to environmental conditions and functional phytoplankton groups
(MacIntyre et al. 2000). Even if photosynthesis performances between different species remain
poorly documented (Goss et Lepetit 2015, Suggett et al. 2015), they can induce a competitive
effect between species at a given time.

512

### 513 **5. CONCLUSIONS**

514 Our study suggests that APS may result from the niche-environment interaction. Our model 515 provides evidence that sharp temporal environmental gradients may be responsible for the strong 516 annual shifts in microphytoplanktonic composition in the North Sea; this occurs when an 517 environmental factor becomes rapidly favourable (e.g. increasing PAR at the end of winter) or 518 limiting (e.g. diminution of macro-nutrients at the end of spring). We identify three key parameters 519 that influence directly the succession: (i) temperature, (ii) PAR and (iii) macro-nutrients. There is 520 a clear effect of temperature on APS with a cline from cold-water species in early spring to warm-521 water species in late summer. By enabling the initiation of the spring bloom and ending the second 522 bloom in autumn, PAR exerts an important role. Macro-nutrients are critical at the end of the spring 523 bloom and their increases in autumn trigger a secondary bloom which then becomes rapidly limited 524 by PAR and temperature. Mixing is an important process by which macro-nutrients increase in the euphotic zone. In the light of our results the shoaling of the pycnocline should not be directly 525 526 involved in bloom initiation (i.e., Sverdrup's hypothesis), however, and the increase in grazing is 527 not determinant for its termination (Behrenfeld's hypothesis).

## 768 Figure legends

Figure 1. Annual changes in the environmental parameters considered in this study. (a) Sea
Surface Temperature (SST), (b) Photosynthetically Active Radiation (PAR), (c) Nitrate, (d)
Silicate, (e) and Phosphate concentrations, and (f) Nitrate/Phosphate (N/P) ratio. Note that SST is
at a daily resolution whereas other parameters are at a monthly one (see Materials and Methods).

**Figure 2. Annual succession of phytoplankton sorted by PCA. (a)** Species positively and (b) negatively correlated with the first principal component (PC1). (c) Species positively correlated with PC2. (d) Species negatively correlated with PC3. Only annual changes in phytoplankton species with normalised eigenvectors negatively (<-0.5) or positively (>0.5) correlated to a corresponding principal component were represented. See Table S1 for information on species and their relations to the PCs. Tot. Sp. Richness: total species richness.

779 Figure 3. Reconstructed annual plankton succession from a one-dimensional model based on 780 SST (Sea Surface Temperature, left panels), PAR (Photosynthetically Active Radiation, 781 middle panels) and nitrate (right panels). A PCA was performed on the relative pseudo-species 782 abundances to identify the most important seasonal phytoplankton abundance patterns. Only 783 predicted plankton seasonal changes, related substantially negatively or positively (i.e., normalised 784 eigenvectors >|0.5|) to the Principal Components (PCs) are shown. SST (a-c): species (a) 785 positively and (b) negatively correlated to PC1, (c) species negatively correlated to PC2. SST: 786 Individual pseudo-species abundance is on the left vertical axis. PAR (d-f): species (d) positively 787 and (e) negatively correlated to PC1, (f) species negatively correlated to PC2. Nitrate (g-i): species 788 (g) positively and (h) negatively correlated to PC1, (i) species negatively correlated to PC2. 789 Relative individual pseudo-species abundances generated from METAL are on the left vertical 790 axis.

# 791 Figure 4. Reconstructed annual plankton succession from a three-dimensional run based on

SST, PAR and nitrate. A PCA was performed on relative individual pseudo-species abundances to identify the most important seasonal patterns in phytoplankton abundance. Only predicted plankton seasonal changes related substantially negatively or positively (i.e., normalised eigenvectors >|0.5|) to the Principal Components (PCs) are shown. Species (a) positively and (b) negatively correlated to PC1. (c) Species negatively correlated to PC2. (d) Species negatively correlated to PC3. (e) Species positively correlated to PC4. Individual pseudo-species abundance is on the left vertical axis.

Figure 5. Seasonal patterns in standardised observed and simulated phytoplankton species
 abundances. Relative abundances of species sampled by the CPR survey (blue) plotted together
 with relative abundances of pseudo-species reconstructed using METAL (orange). See Table S1
 for species names.

Figure 6. Identification of the key environmental parameters for reconstructing annual
 phytoplankton succession. (a) Number of phytoplankton species exhibiting their highest
 correlation for each model (run). See Table S2 for the correspondence between run numbers and
 environmental combinations of variables. (b) Highest correlation for a given phytoplankton
 species and run. The colorbar shows the linear correlation value.

### 864 Supplementary Figures and Tables Legends

Figure S1. Location of the study area. The geographical boundary of the rectangle (black box)
is 54-56°N and 1-4°E.

867

868 Figure S2. Thermal niche (bottom) and the associated theoretical response (top) of a hypothetical species to the fluctuations of an environmental parameter. The optimal value 869 870  $(x_{opt})$  of the ecological niche corresponds to the centre of the species' distributional range and is 871 associated with the highest species' abundance that is located in the optimum zone between the 872 two points  $X_s$ . The bimodal distribution of temporal variability exhibits a maximum  $V_{max}$ 873 corresponding to greatest slopes (XHV; HV for High Variability) of the niche. X<sub>D</sub> is the threshold 874 from where environmental fluctuations are unlikely to be detected because the species' ecological 875 sensitivity becomes too small. X<sub>L</sub> are the values where environmental variability becomes lethal. The grey areas indicate the region where the response of the species to environmental changes is 876 877 expected to be strong. From Beaugrand and Kirby (2016).

878

879 Figure S3. Average correlation (a) and Mean Absolute Error (MAE) (b) for each run used

to reconstruct annual phytoplankton succession from uni-dimensional (1D) to 5-dimensional
 (5D) models. The average value (blue circle) was based on the best correlations (a) or MAEs (b)
 assessed between observed species and (simulated) pseudo-species. Black and red points show the
 results of the same calculations based on a null model with (red) and without (black) consideration
 of temporal autocorrelation.

885

886 Table S1. List of phytoplankton species and their correlation with the first four principal 887 components (PCs). List of phytoplankton species considered in our study area (see Fig. S1). The 888 81 species were grouped in the following classes: 1: Bacillariophyceae, 2: Dinophyceae, 3: 889 Primnesiophyceae, 4: Dictyochophyceae and 5: Cyanophyceae. The first four PCs considered in 890 Fig. 2 and their eigenvalues are reported here. A cross indicates a significant correlation (> |0.5|)891 between a species and a principal component. Some species were not correlated. The percentage 892 of explained variance per principal component is indicated into brackets. The seasonal cycles of 893 each phytoplankton species are represented on Fig. S4 (see species numbers, first column of this 894 table, for correspondence).

895 Table S2. Model simulations. Information on the 84 runs based on all possible combinations of 896 environmental parameters from one (1D; uni-dimensional) to five (5D; 5-dimensional) variables. 897 T: Sea Surface Temperature, Tbis: Sea Surface Temperature using a higher number of niches, 898 PARa,b,c: Photosynthetically Active Radiation (the letters represent 3 different measures used to calculate the optimum values, E.m<sup>-2</sup>.day<sup>-1</sup>; see text and Table S3 for details), N: Nitrate (µmol.L<sup>-</sup> 899 900 <sup>1</sup>). S: Silicate (µmol.L<sup>-1</sup>), P: Phosphate (µmol.L<sup>-1</sup>), N/P: Nitrate/Phosphate ratio (see Table S3 for 901 a better understanding of the selected SST and PAR values). For each run, computation time 902 required for building pseudo-species and calculating species abundances is reported.

903

**Table S3. Environmental variables used for the calculation of pseudo-species abundances** and respective optimum and tolerance values. For each environmental parameter the table shows the different range of optimum values and ecological amplitudes defined for niche construction. We used several resolutions (first column) to calculate the environmental niche. For runs ended by "bis", the resolution was improved to examine model sensitivity related to the number of points used to calculate the niche. To examine the sensitivity of our analysis to PAR, 910 three categories (a, b, c) were determined by selecting different minimum values (see text). When 911 more than one factor was considered, the number of niches was multiplied by each ecological 912 dimension to obtain the total number of niches (see text).

913

914 Table S4. Statistics calculated for the different runs, using several combinations of

915 **environmental parameters.** For each combination of environmental parameters, the number of 916 species, mean and maximum correlation values and probability values that result from the

application of null models for both the Pearson correlation and MAE, with and without

- 918 consideration of temporal autocorrelation, are reported.
- 919
