(Dated: 2 June 2021)

We investigate spectral properties of turbulence in the solar wind that is a weakly collisional astrophysical plasma, accessible to in-situ observations. Using the Helios search coil magnetometer measurements in the fast solar wind, in the inner heliosphere, we focus on properties of the turbulent magnetic fluctuations at scales smaller than the ion characteristic scales, the so-called kinetic plasma turbulence. At such small scales, we show that the magnetic power spectra between 0.3 and 0.9 AU from the Sun have a generic shape $\sim f^{-8/3} \exp(-f/f_d)$ where the dissipation frequency f_d is correlated with the Doppler shifted frequency $f_{\rho e}$ of the electron Larmor radius. This behavior is statistically significant: all the observed kinetic spectra are well described by this model, with $f_d = f_{\rho e}/1.8$. Our results indicate that the electron gyroradius plays the role of the dissipation scale and marks the end of the electromagnetic cascade in the solar wind.

14

Astrophysical plasmas are often very rarefied so that the Coulomb collisions are infrequent [e.g., 37, 52]: in 17 contrast to the usual neutral fluids, the collisional dissipation (viscous and resistive) channels are weak, and the Kolomogorov's dissipation scale [23] is ill-defined. Furthermore, the presence of a background magnetic field B_0 introduces a preferred direction [e.g., 42, 43, 54, 58] and allows the existence of propagating incompressible modes (Alfvén waves). The different plasma ion and electron constituents have a number of characteristic (kinetic) scales at which properties of turbulent fluctuations

Considering all this complexity, one may wonder whether there is a certain degree of generality in space plasma turbulence. In particular, does the dissipation range have a general spectrum, as is the case in neutral fluid turbulence [18, 23]?

The solar wind plasma, which is accessible to in-situ 33 space exploration, has proven to be a very useful laboratory to study the astrophysical plasma turbulence [e.g., 5, 12]. Since the first early in-situ measurements, [e.g., 19, our knowledge of the large-scale turbulence in the solar wind has greatly improved, [e.g., 12, 30]. There 38 is an extended inertial range of scales at which incom-39 pressible magnetohydrodynamics (MHD) phenomenolo-40 gies [9, 13, 24], similar in spirit to Kolomogorov's phe-41 nomenology, may be invoked to understand the forma-42 tion of a Kolmogorov-like spectrum of magnetic fluctu-₄₃ ations $\sim k^{-5/3}$. (Note that satellite measurements are 44 time series, thus, in Fourier space one gets frequency 45 spectra. At the radial distances from the Sun studied

46 here, any characteristic plasma velocity, except whistler 47 wave phase speed, is less than the solar wind speed V. 48 Thus, one can invoke Taylor's hypothesis and convert a 49 spacecraft-frame frequency f to a flow-parallel wavenumber k in the plasma frame $k = 2\pi f/V$.

At the short wavelength end of the inertial domain, 52 i.e., at scales of the order of the proton inertial scale $_{\rm 53}$ λ_p = c/ω_{pp} (where c is the speed of light and ω_{pp} is 54 the proton plasma frequency) the spectrum steepens. At 55 these scales (~ 100 km at 1 AU from the Sun [40]), 56 the MHD approximation is no longer valid; the "heavy" 57 ion (basically, a proton in the solar wind) fluid and the ⁵⁸ "light" electron fluid behave separately, [e.g., 26, 36, 44]. 59 It is still not completely clear whether the spectral steep-60 ening at ion scales is the beginning of the dissipation 61 range or a transition to another cascade taking place between ion and electron scales or a combination of both [e.g., 5, 14, 33]. Recent von Kármán-Howarth analyses 64 of direct numerical simulations and *in-situ* observations 65 [7, 26] indicated that the transition from the MHD iner-66 tial range to the sub-ion range is due to a combination of 67 the onset of the Hall MHD effect and a reduction of the 68 cascade rate likely due to some dissipation mechanism. 69 Then, the question arises as to how much of the dissi-70 pation of the turbulent energy is flowing into the ions 71 and how much is flowing into the electrons. In the vicin-₇₂ ity of the electron scales (~ 1 km at 1 AU), the fluid 73 description no longer holds, and the electrons should be 74 considered as particles. The present paper focuses on this 75 short wavelength range, i.e., between the ion scales and 76 a fraction of the electron scales.

The first solar wind observations of turbulence at scales 78 smaller than ion scales (the so-called *sub-ion scales*) were 79 reported by Denskat et al. [21], using the search coil mag- 137 sub-ion scales [6]. In a statistical study of turbulent spec-

tuations (STAFF) instrument on Cluster space mission 144 the Sun-spacecraft distances sampled by PSP to date. [20, 22], which is the most sensitive SCM flown in the 145 to another, suggesting that the spectrum is not universal 152 erality of the phenomenon. 95 at kinetic scales [34, 50, 51]. However, as was shown in [31, 35, 48], most of these spectral variations are due to 97 the presence, or absence, of quasi-linear whistler waves 153 98 with frequencies at a fraction of the electron cyclotron 99 frequency $f_{ce} = eB_0/(2\pi m_e)$ (where e and m_e are the 100 charge and the mass of an electron, respectively) and wave vectors k quasi-parallel to B_0 [31]. These waves may result from the development of some instabilities associated with either an increase of the electron temperature anisotropy or an increase of the electron heat flux in some regions of the solar wind [56]. In the absence 106 of whistlers, the background turbulence is characterized 107 by low frequencies in the plasma frame and wave vectors mostly perpendicular to the mean field $\mathbf{k} \perp \mathbf{B_0}$ [32]. This quasi-2D turbulence is convected by the solar wind (with the speed V) across the spacecraft and appears in the satellite frame at frequencies $f = k_{\perp}V/2\pi$. It happens that these frequencies are below but close to f_{ce} , exactly in the range where whistler waves (with $k \parallel B_0$ and $f \simeq (0.1 - 0.2) f_{ce}$) may appear locally. Therefore, the superposition of turbulence and whistlers at the same frequencies is coincidental. If we could perform measurements directly in the plasma frame, these two phenomena would be completely separated in k and f. A possible 119 interaction between turbulence and whistlers is out of 120 the scope of the present paper. We focus here on the background turbulence at kinetic scales only.

A statistical study by Alexandrova et al. [4] of solar wind streams at 1 AU under different plasma conditions showed that, in the absence of parallel whistler waves, the quasi-2D background turbulence forms a stant and $T_{e\perp}$ is the electron perpendicular temperature). 184 Such bumps are the signatures of parallel whistler waves the Sun than 1 AU?

wind at 0.17 AU show a spectrum close to $\sim f^{-8/3}$ at 191 ual spectra of Helios–SCM. Here, we analyze background

netometer (SCM) on Helios space mission at radial dis- 138 tra up to 100 Hz, Bowen et al. [11] determined spectral tances $R \in [0.3, 0.9]$ AU from the Sun. From this pio- 139 indices up to 30 Hz, confirming a power law usually obneering work we know that between the ion and electron 140 served at 1 AU $\sim f^{-2.8}$ [2, 4, 15, 29, 51]. The PSP–SCM scales, the magnetic spectrum follows an $\sim f^{-3}$ power 141 data products up to 100 Hz used in [6, 11] and the instru-142 mental noise level do not allow the resolution of electron Thanks to the Spatio-Temporal Analysis of Field Fluc- 143 scales at 0.17 AU, at least for the types of solar wind and

In this paper, we analyze magnetic spectra within the solar wind to date, the small scale tail of the electro- 146 [7,700] Hz range at radial distances between 0.3 and magnetic cascade at 1 AU could be explored down to a 147 0.9 AU thanks to Helios measurements. Here, for the fraction of electron scales $\sim 0.2-1$ km [1, 2, 4, 5, 32, 148 first time, we provide a turbulent spectrum at electron 34, 35, 50, 51], i.e., up to 1/5 of electron scales. These 149 scales and its simple empirical description at distances observations seem confusing at first glance: the spectral 150 from the Sun smaller than 1 AU. The spectrum follows shape of the magnetic fluctuations varies from one record 151 a function similar to that found at 1 AU, indicating gen-

DATA II.

The SCM instrument on Helios space mission [38] con-155 sists of three orthogonally oriented search coil sensors 156 which are mounted on a boom at a distance of 4.6 m 157 from the center of the spacecraft with the z-sensor par-158 allel to the spin axis and x and y sensors in the spin 159 plane. The wave forms from the sensors are processed 160 in an on-board spectrum analyzer. They pass through 8 161 band-pass filters which are continuous in frequency cover-162 age and logarithmically spaced. The central frequencies 163 of the 8 channels are 6.8, 14.7, 31.6, 68, 147, 316, 681 and 1470 Hz. The novel feature for the time of construc-165 tion of the instrument was that the filter outputs were 166 processed by a digital mean-value-computer on board of 167 Helios [39].

Thus, the instrument provides magnetic spectra for two of three components, (B_y, B_z) and rarely (B_x, B_z) , 170 in the Spacecraft Solar Ecliptic reference frame, which 171 is equivalent to the Geocentric Solar Ecliptic frame [41]. 172 The available Helios-SCM products are the spectra inte-173 grated over 8 s. For the present study we use only the ₁₇₄ spectra of B_y . Indeed, the pre-flight noise level for the B_{y} spectra matches well the post-flight noise level, which 176 is not the case for B_z . More details on the instrument and data processing can be found in [39].

We have analyzed 246543 individual B_y -magnetic 179 spectra as measured by SCM on Helios-1 with signal-to-180 noise ratios (SNR) larger than or equal to 2 up to 100 Hz, spectrum $\sim k_{\perp}^{-8/3} \exp(-k_{\perp}\ell_d)$, with a cut-off scale $\ell_{d=181}$ at radial distances from the Sun $R \in [0.3, 0.9]$ AU Among well correlated with the electron Larmor radius $\rho_e = \frac{1}{182}$ them, about 2% of the spectra show spectral bumps be- $\sqrt{2k_BT_{e\perp}}/m_e/(2\pi f_{ce})$ (where k_B is the Boltzmann con- 183 tween the lower hybrid frequency f_{lh} and $\sim 0.25 f_{ce}$ [28]. Such a spectrum with an exponential correction indicates 185 as was shown in [31]. The analysis of these spectra with a lack of spectral self-similarity at electron scales, as in 186 bumps, shows that the signatures of whistlers are mostly the dissipation range of the neutral flow turbulence. How $_{\mbox{\tiny 187}}$ present in the slow wind (V < 500 km/s) and their apgeneral is this kinetic spectrum? Is it observed closer to 188 pearance increases with the distance from the Sun [28]. 189 In the fast wind (V > 600 km/s) and close to the Sun, Parker Solar Probe (PSP) observations in the slow 190 we do not observe signatures of whistlers in 8-s individ¹⁹² turbulence spectra in the fast solar wind, i.e., without ¹⁹³ signatures of whistler waves.

On the basis of this first analysis of 246543 B_y —spectra with a SNR ≥ 2 up to 100 Hz, we can already say that the background turbulence without signatures of whistlers is commonly observed (98% of the analyzed spectra) and its spectral shape is very similar at different radial distances as we will see below, just the amplitude changes. Turbulent level decreases with radial distance [8, 10, 17, 21] and thus further from the Sun, fewer SCM frequencies are resolved. For the statistical study, we will consider 3344 spectra with a SNR larger than or equal to 3 up to 4316 Hz and among them 39 spectra with a SNR \geq 3 up to 681 Hz. All these 3344 spectra are at 0.3 AU.

III. SPECTRAL ANALYSIS

206

Figure 1(a)-(c) show examples of the most intense B_y – spectra as measured by SCM on Helios–1 at 0.3, 0.6 and 0.9 0.9 AU, respectively. For the 3 radial distances from the Sun the raw power spectral densities (PSDs) are shown by red diamonds. The dotted line indicates the noise level of the instrument for the B_y –component. The spectra corrected for the noise contribution by the subtraction of the noise level are shown by blue dots. Vertical red lines give the Doppler shifted kinetic scales. Plasma parameters, characteristic lengths and frequencies corresponding to these spectra are given in Table I.

We perform a least square fit of the 3 corrected spectra with the model function known to describe the kinetic spectrum at 1 AU [4]:

$$P_{\text{model}}(f) = Af^{-8/3} \exp(-f/f_d).$$
 (1)

221 This model has two free parameters: the amplitude of 222 the spectrum A and the dissipation frequency f_d . The 223 result of this fitting is shown by a black solid line in the ²²⁴ 3 cases. The corresponding maximal physical frequencies $_{225}$ f_{max} (the highest frequency where the SNR is ≥ 3 still 226 verifies [3]) together with the results of the fit are given 227 at the end of Table I. At 0.3 AU, the spectrum is well resolved up to $f_{max} = 681$ Hz (the 7th out of the 8 SCM ₂₂₉ frequencies). The electron Larmor radius $\rho_e \simeq 0.4$ km ap-₂₃₀ pears at $f_{\rho e} = V/(2\pi\rho_e) = 325$ Hz (see the right vertical 231 red line). Thus, in this case, turbulence is resolved up to a $_{\mbox{\tiny 232}}$ minimal scale of about $\ell_{min} = V/(2\pi f_{max}) = 0.47 \rho_e$ (see 233 the bottom row of Table I). As expected [8, 10, 17, 21], 234 further from the Sun the intensity of the spectra de- $_{235}$ creases with R: at 0.6 AU, the spectrum is resolved up to 236 316 Hz and at 0.9 AU, it is resolved only up to 147 Hz. 237 In both cases, nonetheless, the electron Larmor radius 238 is resolved as $\rho_e \sim 1/B_0$ increases with R and the corre-239 sponding frequency $f_{\rho e}$ decreases (see vertical red lines in ₂₄₀ Figure 1(b) and (c): $f_{\rho e} = 130 \text{ Hz}$ at 0.6 AU and 110 Hz 241 at 0.9 AU). The observed spectra at 3 radial distances 242 from the Sun are well described by the model, and the 243 dissipation frequency f_d decreases from (183 \pm 5) Hz at ²⁴⁴ 0.3 AU to (56 ± 4) Hz at 0.9 AU, following $f_{\rho e}$.

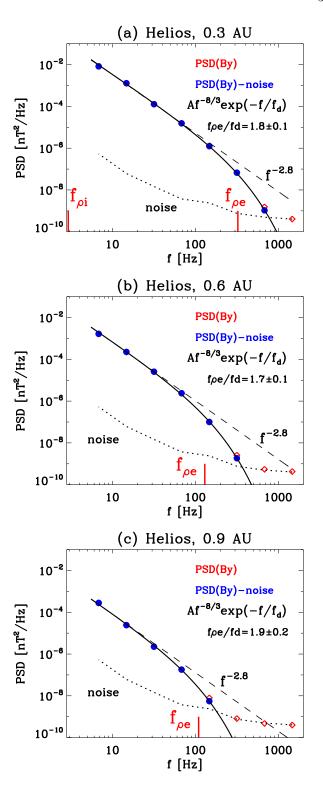

FIG. 1. Examples of the most intense Helios–SCM spectra of B_y component, as functions of the spacecraft-frame frequency f, at (a) 0.3 AU, (b) 0.6 AU and (c) 0.9 AU. For the 3 radial distances, the raw-spectrum is shown by red diamonds, the corrected spectrum, after the subtraction of the noise – by blue dots, the black solid line gives the fit with the model function (1), the dashed line gives $f^{-2.8}$ power-law for comparison and the dotted line indicates the noise level of the Helios-SCM- B_y . Vertical red lines give the Doppler shifted kinetic scales: in (a), ρ_p and ρ_e appear at $f_{\rho p}=2.9$ Hz and $f_{\rho e}=325$ Hz, respectively; in (b) they appear at $f_{\rho p}\simeq 1$ Hz and $f_{\rho e}=130$ Hz, respectively; and in (c) they appear at $f_{\rho p}\simeq 1$ Hz and $f_{\rho e}=110$ Hz, respectively.

TABLE I. Plasma parameters, characteristic scales and frequencies, maximal resolved frequency by Helios/SCM, f_{max} , and results of the fit to Eq.(1) at 3 radial distances from the Sun, corresponding to the spectra in Figure 1. The two bottom rows indicate a fraction of ℓ_d and ρ_e -scales resolved by these spectra.

R (AU)	0.9	0.6	0.3
$B_0 \text{ (nT)}$	8.5	11.6	32.2
V (km/s)	720	710	740
$n_p \; ({\rm cm}^{-3})$	4.8	7.0	28.4

f_d (Hz)	56	58	183
$\Delta f_d/f_d$	0.07	0.04	0.03
f_d/f_{max}	0.38	0.27	0.27
$f_{ ho e}/f_{max}$	0.74	0.40	0.47

of frequencies to fit; thus, we get higher errors.

Now let us consider the most intense spectra, i.e., with $_{253}$ a SNR that is ≥ 3 up to 681 Hz and with simultaneous measurements of B_0 . These conditions are verified for 39 spectra at 0.3 AU in the fast wind, measured during the closest approach of Helios to the Sun.

All these spectra are similar to that shown in Fig- 289 ²⁵⁸ ure 1(a). We perform a least squares fit of the 39 spectra ²⁹⁰ by crosses. The 39 most intense spectra are marked by with the model function, Eq. (1). The relative errors, 291 green crosses; the noise level for B_y , $P_{\text{noise}}(f)$ is indi- $_{260}$ $\Delta f_d/f_d$ and $\Delta A/A$, vary between 0.01 and 0.14. The $_{292}$ cated by the dotted line. Figure 4(b) shows these 3344 261 dissipation scale ℓ_d can be estimated using the Taylor hy- 293 spectra corrected for the noise contribution, P(f)=262 pothesis $\ell_d = V/(2\pi f_d)$. It is found to be correlated with 294 $P_{\text{raw}}(f) - P_{\text{noise}}(f)$, and as functions of f normalised 263 the ρ_e scale with a correlation coefficient C=0.68. The 295 to the Doppler shifted electron Larmor radius frequency, relation $\ell_d \sim 1.8 \rho_e$ is observed (see Figure 2). There is no $_{296}$ $f_{\rho e} = V/(2\pi \rho_e)$. Let us now superpose all spectra to-265 correlation with the electron inertial length λ_e (C=0.02, 297 gether. Figure 4(c) shows a 2D histogram calculated with

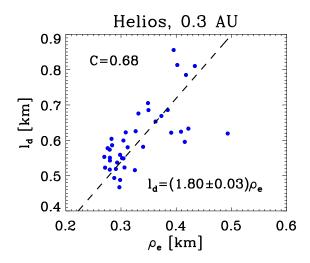

FIG. 2. Results of the fitting procedure of the most intense spectra at 0.3 AU with Eq. (1): dissipation scale $\ell_d = V/2\pi f_d$ as a function of the electron Larmor radius ρ_e ; the linear dependence $\ell_d = 1.8\rho_e$ is indicated by the dashed line, with the correlation coefficient C = 0.68.

266 not shown). Thus, we can fix f_d in Eq. (1):

$$P_{\text{model}}(f) = Af^{-8/3} \exp(-1.8f/f_{\rho e}).$$
 (2)

²⁶⁷ Let us now verify whether this simpler model describes a larger statistical sample.

To increase the number of spectra analysed, we now 270 also consider less resolved spectra, i.e., with a signalto-noise ratio larger than 3 up to 316 Hz, and with plasma measurements in the vicinity of the spectra (i.e., 273 the mean field at most within 16 s around the mea-274 sured SCM spectrum, the electron temperature T_e within 275 about 30 min; and when not available, T_e is taken within From Table I one can see that further from the Sun, 276 a longer time interval but within the same wind type). the relative errors on free parameters of the fit, $\Delta f_d/f_d$ 277 These conditions are verified for 3344 spectra at 0.3 AU in and $\Delta A/A$, increase, while the f_{max} decreases. This error 278 the fast wind. Probability distribution functions (PDFs) increase is expectable: f_{max} is proportional to the turbu- 279 of the mean plasma parameters for the 3344 spectra are lence level, and the lower turbulence level corresponds to 280 shown in Figure 3 with black lines and those for the 39 the smaller SNR and automatically to a smaller number 281 most intense spectra analyzed above, are shown by green 282 lines. The proton β_p (electron β_e) plasma beta is the ra-283 tio between the proton (electron) thermal pressure and the magnetic pressure. From these PDFs, we see that the 39 most intense spectra are observed for the solar wind with V > 650 km/s, for the proton thermal pressure $_{\text{287}}$ $n_{p}k_{B}T_{p} \geq 0.2$ nPa and for the largest β_{p} and β_{e} values of the analyzed data set (for $\beta_p \geq 0.3$ and $\beta_e \geq 0.1$).

Figure 4(a) displays the 3344 raw B_y spectra, $P_{\text{raw}}(f)$,

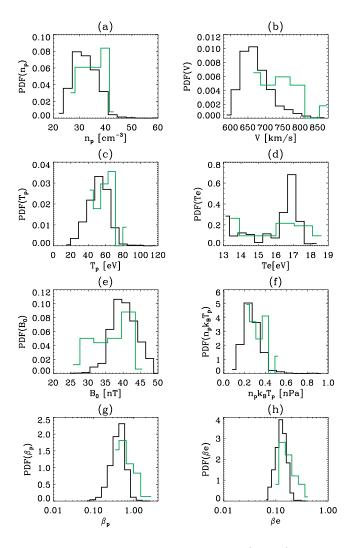

FIG. 3. Probability distribution functions (PDF's) of the mean plasma parameters at 0.3 AU for the 3344 spectra shown in Figure 4 (black lines) and for the 39 most intense spectra (green lines): (a) proton density n_p , (b) solar wind speed V, (c) proton temperature T_p , (d) electron temperature T_e , (e) magnetic field magnitude B_0 , (f) proton thermal pressure $n_p k_B T_p$, (g) proton plasma beta β_p , (h) electron beta β_e .

the spectra of the middle panel and rescaled by their amplitude at $f/f_{\rho e}=0.051$, i.e., $P(f)P_0/P(f_0)$. This means that by construction all spectra pass through the point $(f_0,P_0)=(0.051f_{\rho e},10^{-4}{\rm nT}^2/{\rm Hz})$; the spectrum amplitudes at f_0 are linearly interpolated from the two nearest points. The results do not change if we choose another way to adjust the amplitudes in order to bring the spectra together. This rescaling allows us to fix the last free parameter in Eq. (2), the amplitude to a value A_0 , which is now related to P_0 at f_0 . Thus, we can compare the shape of 3344 spectra with the function

$$P_{\text{model}}(f/f_{\rho e}) = A_0(f/f_{\rho e})^{-8/3} \exp(-1.8f/f_{\rho e}).$$
 (3)

309 This model passes through the data without any fitting;

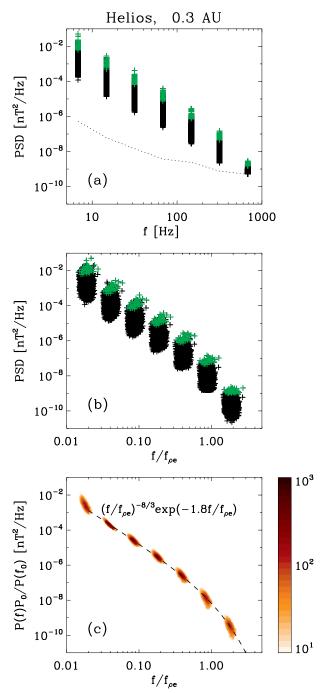

FIG. 4. (a) 3344 individual Helios–1 SCM spectra of B_y as functions of the spacecraft-frame frequency f at 0.3 AU in the fast wind; the 39 most intense spectra are marked by green crosses; the SCM noise for B_y component is indicated by a dotted line. (b) These 3344 spectra corrected for the noise contribution as functions of f normalised to the Doppler shifted electron Larmor radius frequency $f_{\rho e} = V/(2\pi\rho_e)$. (c) The same spectra, rescaled by their amplitude at $f_0 = 0.051 f/f_{\rho e}$ (see the text); the result is shown as a 2D histogram with the number of the data points proportional to the darkness of the red colour. The dashed line displays the model function, Eq.(3).

310 only the frequency is normalized to $f_{\rho e}$, and the am-311 plitude is rescaled at the point (f_0, P_0) , see the dashed 312 line in Figure 4(c). Note that the dispersion of the data 313 points at the lowest and highest frequency ends can be $_{314}$ due to the non simultaneous T_e measurements. More-315 over, the lowest frequency can be affected as well by the 316 proximity of the ion characteristic scales, and the highest 317 frequencies can be affected by the SCM noise.

IV. CONCLUSION AND DISCUSSION

318

These results together with the previous observations 320 at 1 AU [4], indicate that at kinetic scales smaller than the ion characteristic scales, the spectrum in the fast wind keeps its shape $\sim f^{-8/3} \exp(-f/f_d)$ independently of the radial distance from the Sun, from 0.3 to 1 AU, with an exponential falloff, reminiscent of the dissipation range of the neutral fluid turbulence. The equiv-326 alent of the Kolmogorov scale ℓ_d , where the dissipation 327 of the electromagnetic cascade is expected to take place, 328 is controlled by the electron Larmor radius ρ_e for these 329 radial distances. Precisely, here, with Helios we find $_{330}$ $\ell_d \simeq 1.8 \rho_e$, and previously, with Cluster at 1 AU, we ob- $_{365}$ these theoretical and numerical works, the particle disserved $\ell_d \simeq 1.4 \rho_e$ [4]. The constant in front of ρ_e seems 366 tributions are assumed to be Maxwellian, which is not $_{332}$ to be weakly dependent on R. This will be verified in a $_{367}$ the case in solar wind. future study with PSP and Solar Orbiter.

335 sult. First, the electron Larmor radius is not the only 370 observed that the spectral curvature at electron scales is Sun, the electron inertial length λ_e becomes larger than 372 simulations, where the direction parallel to B_0 is not re-₃₃₈ the Larmor radius ρ_e , but as observed here, it is still ₃₇₃ solved, so that the Landau damping cannot be effective. 339 with ρ_e and not with λ_e that the "dissipation" scale cor- 374 Rudakov et al. [49] studied the weak KAW turbulence 340 relates. Second, in neutral fluids, the dissipation scale 375 and showed that a non-Maxwellian electron distribution $_{341}$ ℓ_d is much larger than the mean free path, so that the $_{376}$ function has a significant effect on the cascade: the lin-342 dissipation range is described within the fluid approxi- 377 ear Landau damping leads to the formation of a plateau mation. In the solar wind between 0.3 and 1 AU, as we $_{378}$ in the parallel electron distribution function $f(V_{e\parallel})$, for showed, ℓ_d is defined by ρ_e scale. In the vicinity of ρ_e the $_{379}$ $V_A < V_{e\parallel} < V_{e,th}$, which reduces the Landau damping 345 protons are completely kinetic, and electrons start to be 380 rate significantly. These authors studied the nonlinear 346 kinetic. Third, it appears puzzling that the dissipation 381 scattering of waves by plasma particles and concluded 347 scale in space plasma is fixed to a given plasma scale. It is 382 that, for the solar wind parameters, this scattering is well known in neutral fluids that the dissipation scale ℓ_d 383 the dominant process at kinetic scales, with the dissipation $_{349}$ depends on the energy injection rate ε and thus on the $_{384}$ tion starting at the λ_e scale. To date, we have not mea-350 amplitude of turbulent spectrum in the following way: 385 sured in the solar wind a plateau in $f(V_{e||})$ between the $_{351}$ $A \sim \varepsilon^2/3 \sim \ell_d^{-8/3}$ [e.g., 2, 23]. Is ρ_e independent of the $_{386}$ Alfvén speed V_A and the electron thermal speed $V_{e,th}$. $_{352}$ energy injection? We found previously that the turbulent $_{387}$ Such a distribution may exist, but would be very diffi- $_{353}$ spectrum amplitude is anticorrelated with ρ_e [2]; that is, $_{388}$ cult to observe because of instrumental effects such as 354 it seems that the electron Larmor radius is sensitive to 389 the spacecraft potential and photoelectrons. However, it 355 the turbulence level and thus to the energy injection. We 390 is not clear to what extent the quasi-linear results based 356 expect to verify this point with PSP and Solar Orbiter 391 on the Landau damping or the weakly non-linear model data in future studies.

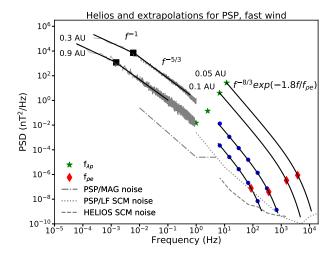

the ρ_e scale the electron Landau damping is at work 394 turbulent power spectrum on kinetic scales. 360 to dissipate magnetic fluctuations into electron heating: 395 Let us now put our observations in a more general con-361 this is found in 3D gyrokinetic simulations [57] and in 396 text of the solar wind turbulence. Figure 5 shows a com-362 analytical models of strong kinetic Alfvén wave (KAW) 397 plete turbulent spectrum covering the energy containing

[49] are relevant when non-linear co-The results presented here may suggest that around 393 herent structures [25, 47] importantly contribute to the

turbulence [46, 53] and can be explained by the weak- $_{398}$ scales ($\sim f^{-1}$ spectral range), the inertial range at MHD $_{364}$ ened cascade model of Howes et al. [27]. However, in $_{399}$ scales ($\sim f^{-5/3}$ range), and the kinetic scales, as ob-

The complete turbulent spectrum from energy injection scales up to the sub-electron scales at 0.3 and 0.9 AU as measured by Helios. The energy containing scales (which correspond to $\sim f^{-1}$ spectrum) and the MHD inertial range ($\sim f^{-5/3}$) are covered by the Helios-MAG instrument (gray lines). The Helios-SCM instrument covers the kinetic scales (blue dots), studied in the present paper. The black solid lines indicate model functions \hat{f}^{-1} , $f^{-5/3}$ and $f^{-8/3} \exp(-1.8f/f_{\rho_e})$ at different frequency ranges. The two most energetic spectra at high frequencies are the extrapolations of the kinetic spectrum in the fast wind that we expect to measure with PSP at 0.05 and 0.1 AU. The dashed line gives Helios-SCM noise, the dashed-dotted and dotted lines the transition from the inertial to the kinetic range; the electron Larmor radius ρ_e (red diamonds) marks the dissipation cutoff.

400 served at 0.3 and 0.9 AU by Helios in the fast wind. The 401 mean plasma parameters for the time intervals used here 447 402 are given in Table II.

cies in Figure 5 are the extrapolations of the kinetic spec- $\,$ $_{452}$ manuscript. trum that we expect to observe in the fast solar wind with 453 ⁴⁰⁸ PSP at 0.05 and 0.1 AU (see the Appendix for more de- ⁴⁵⁴ data archive (http://helios-data.ssl.berkeley.edu/). 409 tails). Indeed, the beginning of this kinetic spectrum 455 following an $f^{-8/3}$ -law between ~ 10 and 100 Hz was 456 model, Eq.(1), is optimize.curve_fit from scipy/python 411 recently observed by PSP at 35.7 solar radii (0.166 AU) 457 [59]. 412 [6, 11]. Future PSP observations closer to the Sun will 458

414 given here may change.

APPENDIX: EXTRAPOLATION OF TURBULENT SPECTRA CLOSER TO THE SUN

To plot the extrapolations of the kinetic spectra at 0.05 418 and 0.1 AU in Figure 5, we assume that the turbulence 419 level will increase together with the mean field, keeping $\delta B/B_0 \sim \text{const}$, as observed in the solar wind, [e.g., 8, 10]. In the inner heliosphere, where $\beta < 1$, the end of the Kolmogorov scaling is expected to happen at the proton inertial length λ_p [10, 16] (see green stars). The exponential falloff at the end of the electromagnetic cascade 425 is defined by the local ρ_e , as we confirm in this study. To 426 determine the Doppler shifted frequencies where λ_p and 427 ρ_e will appear in the extrapolated spectra $(f_{\lambda p} = V/2\pi\lambda_p)$ 428 and $f_{\rho e} = V/2\pi \rho_e$), we use plasma parameters (proton 429 density n_p , electron temperature T_e , magnetic field B_0 , 430 and solar wind speed V) extrapolated from the in-situ Helios measurements (from 0.3 to 0.9 AU). These latter 432 extrapolations have been performed by connecting the 433 gradient of the Helios density measurements to the one 434 measured remotely from coronal white light eclipse ob-435 servations. More precisely, we have retrieved the radial 436 variations of both the electron density $n_e(R)$ (which we 437 assume for simplicity to be equal to $n_n(R)$ and bulk 438 speed V(R) all the way down to the low corona by (i) 439 imposing that the density matches both the 0.3 to 1 AU 440 Helios density observations and the coronal density observations obtained remotely by Sittler and Guhathakurta 442 [55] and (ii) imposing the conservation of the mass flux indicate noise levels of the different magnetic sensors on PSP. 443 $n_e(R)V(R)R^2 = \text{const.}$ The plasma parameters used for The Doppler shifted ion inertial length λ_p (green stars) marks 444 the extrapolated spectra as well as for the time intervals of the Helios measurements are summarized in Table II.
