Chiesa^{1,3,4}, Enrica Cavedo^{1,3,4,6}, Pablo Lemerrier^{1,3,4}, Henrik Zetterberg^{7,8,9,10}, Kaj Blennow^{7,8}, Marie-Odile Habert^{11,12,13}, Marie Claude Potier¹⁴, Bruno Dubois^{1,3,4}, Andrea Vergallo¹, Harald Hampel¹, the INSIGHT-preAD study group and for the Alzheimer Precision Medicine Initiative (APMI)

Abstract

Background: Plasma neurofilament light (NFL) and total Tau (t-Tau) proteins are candidate biomarkers for early stages of Alzheimer's disease (AD). The impact of biological factors on their plasma concentrations in individuals with subjective memory complaints (SMC) has been poorly explored. We longitudinally investigate the effect of sex, age, *APOE* $\epsilon 4$ allele, comorbidities, brain amyloid- β ($A\beta$) burden, and cognitive scores on plasma NFL and t-Tau concentrations in cognitively healthy individuals with SMC, a condition associated with AD development.

Methods: Three hundred sixteen and 79 individuals, respectively, have baseline and three-time point assessments (at baseline, 1-year, and 3-year follow-up) of the two biomarkers. Plasma biomarkers were measured with an ultrasensitive assay in a mono-center cohort (INSIGHT-preAD study).

Results: We show an effect of age on plasma NFL, with women having a higher increase of plasma t-Tau concentrations compared to men, over time. The *APOE* $\epsilon 4$ allele does not affect the biomarker concentrations while plasma vitamin B12 deficiency is associated with higher plasma t-Tau concentrations. Both biomarkers are correlated and increase over time. Baseline NFL is related to the rate of $A\beta$ deposition at 2-year follow-up in the left-posterior cingulate and the inferior parietal gyri. Baseline plasma NFL and the rate of change of plasma t-Tau are inversely associated with cognitive score.

Conclusion: We find that plasma NFL and t-Tau longitudinal trajectories are affected by age and female sex, respectively, in SMC individuals. Exploring the influence of biological variables on AD biomarkers is crucial for their clinical validation in blood.

Introduction

Plasma neurofilament light (NFL) chain and total Tau (t-Tau) proteins are promising biomarkers of Alzheimer's disease (AD). They show good/fair diagnostic accuracy to distinguish cognitively healthy individuals from AD patients, when ultrasensitive technologies of measurement are used [1–7]. Both proteins are involved in the physiological processes of neuronal integrity [8, 9]. Both plasma t-Tau and NFL are associated with worsening rate of cognitive performance [3, 10–13], cerebral atrophy [2, 3, 12–14], and hypometabolism [2, 3, 12] in prodromal and dementia phases of AD. Only a few studies investigated these biomarkers, either separately [15–18] or in combination [3], during the preclinical stages of sporadic AD. Even less data are available on the effect of key biological factors—such as age, sex, and *APOE* $\epsilon 4$ allele—on plasma NFL and t-Tau concentrations. At our knowledge, there are no studies investigating the potential contribution of comorbidities in affecting either plasma NFL or t-Tau concentrations, and no evidence on the impact of these key biological factors on plasma NFL and t-Tau concentrations in populations with SMC, a condition associated with AD development.

Our primary aims are to investigate, in a cohort of cognitively intact individuals with subjective memory complaints (SMC), the dynamic trajectories of plasma NFL and t-Tau concentrations and the impact of sex, age, and *APOE* genotype. Secondary aims are (1) to identify, at baseline, the variables maximally contributing to group separation of individuals above or below the third quartile for baseline NFL and t-Tau concentrations, respectively; (2) to investigate the association of the two plasma biomarkers, at baseline, with baseline global and regional brain amyloid- β (A β) deposition, A β changes deposition, baseline Mini-Mental State Examination (MMSE) score, Free and Cued Selective Rating Test (FCSRT), the concentrations of the corresponding cerebrospinal fluid (CSF) biomarkers (CSF NFL and CSF t-Tau), and between each other; and (3) to explore the association of NFL and t-Tau changes with MMSE and FCSRT modifications.

Materials and methods

We performed a longitudinal investigation in 316 SMC participants of the French monocentric “INveStIGATION of AlZheimer's PredicTors in Subjective Memory Complainers” (INSIGHT-preAD) cohort (Pitié-Salpêtrière University Hospital, Paris) [19]. All participants underwent two A β -positron emission tomography (A β -PET) scans, at baseline and at 2-year follow-up. A subset of 40 individuals received a baseline lumbar puncture. The concentrations of plasma NFL and t-Tau were measured at three time points using an ultrasensitive technology ($N = 79$ at baseline, 1-year, and 3-year follow-up).

Study participants

We designed a large-scale mono-centric research program using a cohort of SMC recruited from the INSI GHT-preAD study, a French academic university-based cohort [19] which is part of the Alzheimer Precision Medicine Initiative (APMI) and its Cohort Program (APMI-CP) [20–23]. Participants were enrolled between May 25, 2013, and January 20, 2015, at the Institute of Memory and Alzheimer's disease (*Institut de la Mémoire et de la Maladie d'Alzheimer*, IM2A) at the Pitié-Salpêtrière University Hospital in Paris, France [19]. The study was conducted in accordance with the tenets of the Declaration of Helsinki of 1975 and approved by the local Institutional Review Board at the participating center. All participants gave written informed consent for use of their clinical data for research purposes.

PET data acquisition and processing

All Florbetapir-PET scans were acquired in a single session on a Philips Gemini GXL CT-PET scanner 50 (± 5) min after injection of approximately 370 MBq (333–407 MBq) of Florbetapir. Images acquisition, reconstruction including correction algorithms and reallination, averaging, and quality check were performed by the CATI team (*Centre d'Acquisition et Traitement des Images*) (<http://cati-neuroimaging.com>) [19, 24, 25] and were calculated for each of 12 cortical regions of interest (right and left posterior cingulate, right and left anterior cingulate, right and left superior frontal, right and left inferior parietal, right and left precuneus, right and left middle temporal cortices), as well as the global average standard uptake value ratio (SUVR).

CSF sampling and biomarkers assessment

CSF sampling was performed by lumbar puncture in a subsample of 40 individuals. All CSF samples were collected in polypropylene tubes, centrifuged at 1000 g for 10 min at $+4^\circ\text{C}$. The collected supernatant was stored at -80°C for pending biochemical analysis. The immunoassays for CSF core biomarkers are reported in previous studies [26, 27].

Blood sampling and collection tube storage

Ten (10) mL of venous blood were collected in one BD Vacutainer® spray-coated K2 tube, which was employed for all subsequent immunological analyses. Blood samples were taken in the morning, after a 12-h fast, handled in a standardized way, and centrifuged for 15 min at 2000 G-force at $+4^\circ\text{C}$. Per sample, plasma fraction was collected, homogenized, aliquoted into multiple 0.5 mL cryovial-sterilized tubes, and finally stored at -80°C within 2 h from collection.

Immunoassays for plasma biomarkers

All analyses of plasma t-Tau and NFL concentrations were performed at the Clinical Neurochemistry Laboratory, Sahlgrenska University Hospital, Sweden [28–30]. In particular, a volume of 0.5 mL of plasma for each individual was required for performing the analyses.

Plasma t-Tau concentrations were measured using the Human Total Tau 2.0 kit on the ultrasensitive single molecule arrays (Simoa) platform (Quanterix, Lexington, MA), according to the manufacturer instructions.

For plasma t-Tau, both repeatability and intermediate precision were 12.2% for an internal QC plasma sample with a concentration of 1.9 pg/mL [2, 30]. The t-Tau assay was originally developed in a collaboration between the Clinical Neurochemistry Laboratory and Quanterix [31]. However, the commercially available assay was built on this work but with another set of antibodies.

Plasma NFL concentrations were measured using the ultrasensitive Simoa technology, according to the manufacturer instructions. Repeatability was 9.6% and 10.6% and intermediate precision was 14.6% and 11.6% for two internal QC plasma samples with concentrations of 12.9 pg/mL and 107 pg/mL [28–30]. The NFL assay was originally developed by the Clinical Neurochemistry Laboratory and then commercialized by Quanterix [32].

All samples were analyzed on one occasion using one batch of reagents by board-certified laboratory technicians who were blinded to clinical data.

Statistical analysis

Statistical analysis was performed using IBM-SPSS® Statistics, Version 20, and Addinsoft, XLSTAT Statistical and Data Analysis Solution (2019), Long Island, NY, USA, statistical packages for Mac OS X.

Kolmogorov-Smirnov test was applied to check for normality. Gaussian distributed values were expressed as mean and standard deviation (SD) or standard error (SE); otherwise, median and interquartile range (IR) were used for quantitative variables, while categorical data were expressed as frequency.

To evaluate the impact of age, sex, and *APOE* $\epsilon 4$ carrier status on NFL and t-Tau evolution in a 3-year follow-up, respectively, we conducted two independent linear mixed-effects models (LMM) on the whole sample [33]. Age, sex, and *APOE* $\epsilon 4$ carrier status were included as fixed effects in the model and each individual as random effect. We also included interaction between age and sex, age and *APOE* $\epsilon 4$ carrier status, and sex and *APOE* $\epsilon 4$ carrier status. Type III likelihood ratio tests were used to test each fixed effect and interaction. The statistical models used were verified for normal distribution of residuals, random effects, and homoscedasticity of residuals. Subsequently, the analysis was repeated

after stratifying the sample into amyloid-PET-negative and positive individuals.

On the whole sample, cross-sectional data were also elaborated to identify the variables maximally contributing to group separation of individuals, based on the following outcome variables Y: baseline plasma NFL and baseline plasma t-Tau. To this end, two partial least square (PLS) models were generated, and the variables with Variable Importance in Projection (VIPs, expressing a measure of a variable's relevance in the model) greater than 1.50 were considered significant for separation of the sample [34, 35]. In the first model, Y was defined by placing NFL = 1 whether NFL concentrations were above or below the third quartile, and 0 if below. Input variables were sex, age, *APOE* $\epsilon 4$ carrier status, arterial hypertension, (HTA), atrial fibrillation, heart disease, dyslipidemia, diabetes, obstructive sleep apnea syndrome (OSAS), head trauma, mood disorders, vitamin B12 deficiency, body mass index (BMI), global SUVR, MMSE and FCSRT at baseline, and baseline plasma t-Tau. In the second model, input variables were the same, as previously described, but the outcome variable Y was t-Tau, categorized as 1 if t-Tau concentrations were upper than the third quartile, and 0 otherwise.

The associations of the two plasma biomarkers at baseline with baseline global and regional brain A β deposition, Δ A β deposition, baseline MMSE score, FCSRT, the corresponding CSF biomarkers, and between each other were evaluated by Spearman correlation testing. If the relationship was significant, a subsequent stepwise forward regression was performed. Spearman test was used to explore the association of Δ NFL and Δ t-Tau with Δ MMSE and Δ FCSRT (cognitive measures). Δ value has been defined as the difference between the baseline and the 3-year follow-up value, excluding for A β deposition where we considered 2-year follow-up value, because we had the baseline data available and after 2 years.

Variables with skewed distribution were log-transformed for use in all parametric analyses. *P* values < 0.05 were considered significant in all statistical elaboration.

Results

The clinical and demographic baseline characteristics of the 316 participants also stratified by sex are reported in Table 1. Seventy-nine individuals had all time point plasma samples (at baseline, 1-year, and 3-year follow-up). In these individuals, NFL and t-Tau longitudinal data (Figs. 1a and 2a), also stratified by sex (Figs. 1b and 2b), using within person trajectories (Figs. 1c and 2c), are shown. After a 3-year follow-up, six SMC individuals (~2%) clinically progressed to mild cognitive impairment (MCI) or dementia (Table 1S).

Plasma NFL, t-Tau biomarkers and biological variables

The impact of biological factors on plasma biomarkers concentration over time

Table 2 summarizes the main effects investigated for NFL and t-Tau, respectively. For the whole sample, we found a significant effect of age on plasma NFL concentrations ($P < 0.001$), but not of sex and of age*sex interaction. When we performed a post hoc analysis, after dividing the sample into groups of less than and above 76 years of age (value corresponding to average, median and mode), the individuals over 76 years of age showed higher NFL values in all time points considered (mean and SE at baseline: 32.5 ± 1.1 and 27.0 ± 0.9 pg/mL, respectively, $P < 0.001$; at 1-year follow-up: 34.8 ± 1.4 and 27.6 ± 1.2 pg/mL, respectively, $P < 0.001$; at 3-year follow-up: 58.2 ± 3.5 and 49.9 ± 2.7 pg/mL, respectively, $P = 0.049$). When we repeated the analysis, after stratifying by cerebral amyloid-PET-negative and amyloid-PET-positive individuals, we have obtained comparable results. In the amyloid-PET-negative subgroup, the post hoc analysis, after dividing the sample into subsets of less than and above 76 years of age, the individuals over 76 years of age showed higher NFL values in all time points considered (mean and SE at baseline: 31.3 ± 1.3 and 26.2 ± 1.0 pg/mL, respectively, $P = 0.002$; at 1 year: 33.6 ± 1.8 and $28.1 \pm$

1.5 pg/mL, respectively, $P = 0.019$; at 3 years: 53.8 ± 2.5 and 47.2 ± 2.3 pg/mL, respectively, $P = 0.050$). Again, in amyloid-PET-positive individuals, those over 76 years of age reported higher NFL values (mean and SE at baseline: 35.1 ± 2.1 and 30.4 ± 2.4 pg/mL, respectively, $P = 0.050$; at 1 year: 38.0 ± 2.6 and 27.3 ± 2.7 pg/mL, respectively, $P = 0.006$; at 3 years: 67.8 ± 3.9 and 57.6 ± 3.9 pg/mL, respectively, $P = 0.049$).

APOE ε4 allele had no effect on the total sample and amyloid-PET-negative individuals. However, on amyloid-PET-positive individuals, at 3 years of follow-up, NFL was significantly higher in ε4+ individuals compared to ε4− (mean and SE: 64.1 ± 7.3 and 46.2 ± 3.3 pg/mL, respectively, $P = 0.040$). No interaction with APOE ε4 carrier status was found in any group.

In the total sample, a significant effect of sex on plasma t-Tau concentrations was reported, displaying higher means in female than in male individuals ($P = 0.001$) (Table 2). The significant sex*age interaction ($P = 0.038$) indicated that this effect was not the same among the different ages. In particular, at 3 years of follow-up, t-Tau concentrations were higher in male individuals aged more than 76 years than in those younger (mean and SE = 6.2 ± 0.8 and 4.5 ± 0.3 pg/mL, respectively, $P = 0.040$) but not in women (mean and SE = 5.2 ± 0.3 and 5.7 ± 0.4 pg/mL, respectively, $P = 0.359$). No significant differences in male or female

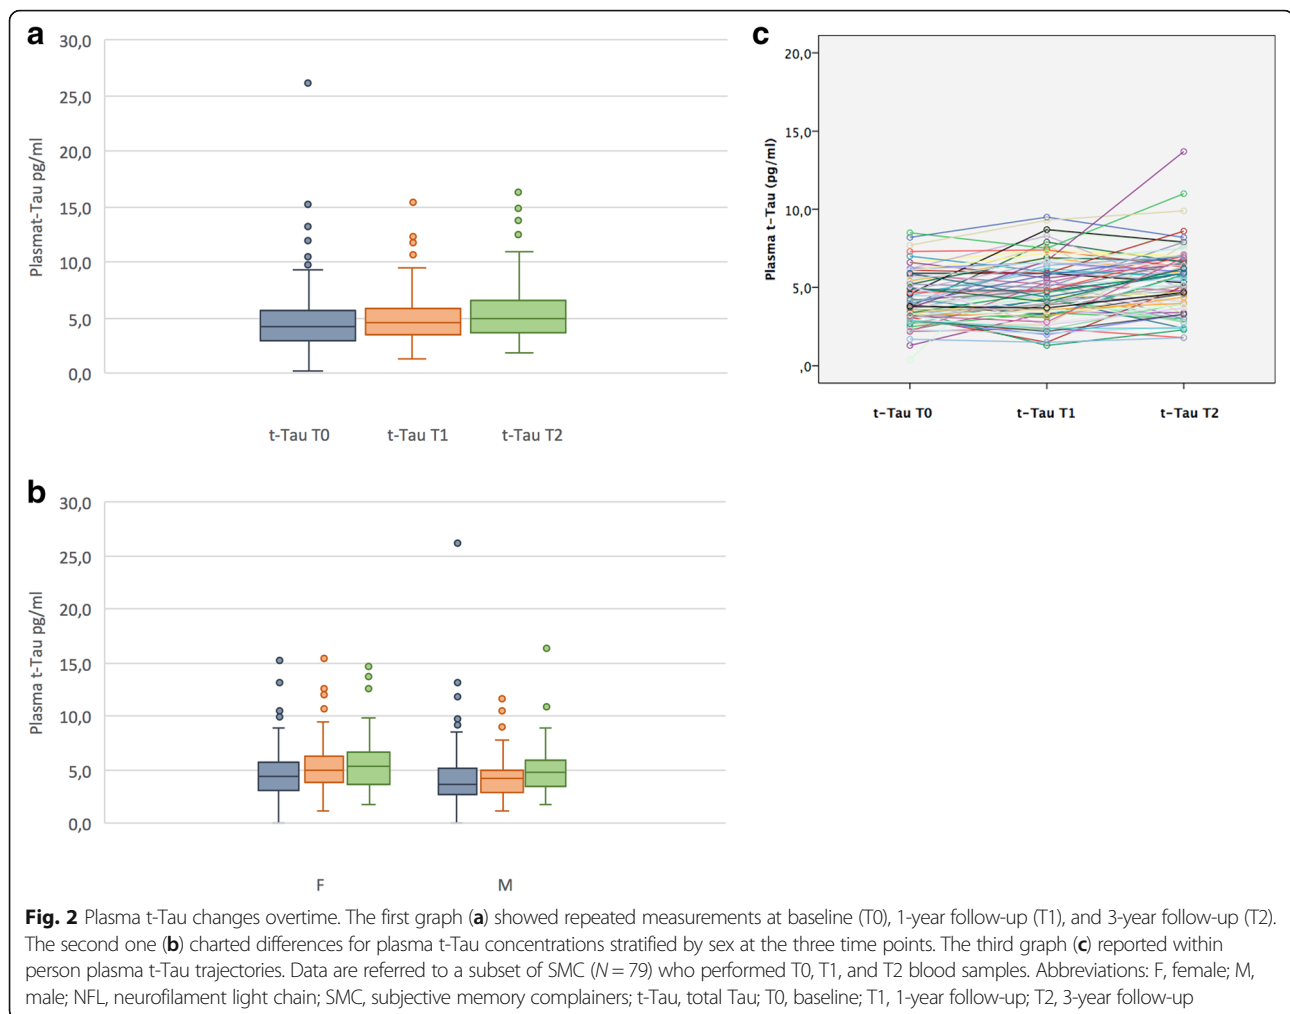

individuals for baseline and 1 year of follow-up have been observed. When we repeated the analysis, after stratifying participants in cerebral amyloid PET negative and positive, we found similar results in both subgroups, with no significant difference for the baseline and at 1 year of follow-up. Regarding the 3-year follow-up, for amyloid positive individuals, t-Tau concentrations were higher in males aged more than 76 years than in those younger (mean and SE: 7.6 ± 2.1 and 5.5 ± 1.9 pg/mL, respectively, $P = 0.048$), but not in women (mean and SE = 4.9 ± 0.6 and 6.4 ± 1.2 pg/mL, respectively, $P = 0.220$). We found similar results in amyloid-PET-negative individuals: higher concentrations in men aged more than 76 years than in those younger (mean and SE: 5.5 ± 0.6 and 4.0 ± 0.3 pg/mL, respectively, $P = 0.032$) and not in women (mean and SE: 5.5 ± 0.4 and 5.4 ± 0.3 pg/mL, respectively, $P = 0.886$). We did not detect a significant effect of *APOE* $\epsilon 4$ allele on plasma t-Tau concentrations nor a significant interaction between *APOE* $\epsilon 4$ allele and sex, nor between *APOE* $\epsilon 4$ allele and age, both in the total sample and after splitting whole sample in amyloid-PET-negative and positive individuals.

Biological factors contributing to high baseline plasma biomarker concentrations

Using baseline NFL as a dependent variable, PLS identified the following variables separating the sample on the basis of NFL concentrations above or below the third quartile: age (VIPs = 2.74) and plasma baseline t-Tau (VIPs = 1.53). The participants with NFL concentration above the third quartile are older and had higher t-Tau concentrations than the others (Table 3). In the second PLS model, the parameters identifying individuals with t-Tau = 0/1 were plasma vitamin B12 deficiency (VIPs = 2.48) and sex (VIPs = 1.83). Individuals with plasma t-Tau concentrations above the third quartile (t-Tau = 1) were more significantly represented by women than men (females = 76%, males = 24%). Individuals with plasma vitamin B12 deficiency showed plasma t-Tau concentrations above the upper quartile (Table 3).

Plasma biomarkers and cerebral amyloid load

No association between baseline plasma NFL or t-Tau concentrations and both baseline and 2-year follow-up

cerebral A β deposition were reported. Baseline plasma NFL concentrations were weakly associated with global brain amyloid increase over time (Δ SUVR, $\rho_s = 0.15$; $P = 0.030$). When a subsequent stepwise forward regression using baseline plasma NFL as a dependent variable was performed, a relationship with Δ amyloid deposition in the left posterior cingulate and in the bilateral inferior parietal gyri has been observed ($r = 0.13$; $P = 0.019$ and $r = 0.14$; $P = 0.013$, respectively). Furthermore, baseline plasma NFL concentration was associated with plasma t-Tau ($\rho_s = 0.18$; $P = 0.011$) and CSF NFL ($\rho_s = 0.90$; $P < 0.001$). In Table 4, we charted a summary of the associations between plasma biomarkers and cerebral amyloid load.

Plasma biomarkers and cognition

No association between baseline plasma NFL or t-Tau concentrations and baseline MMSE score or FCSRT was observed. Baseline plasma NFL concentrations negatively correlated with MMSE at 3-year follow-up ($\rho_s = -0.13$; $P = 0.029$). No association with FCSRT was observed. Δ t-Tau correlated inversely with MMSE ($\rho_s = -0.19$; $P =$

0.015) and positively with Δ NFL ($\rho_s = 0.30$; $P < 0.001$) at the 3-year follow-up. In Table 4, we reported a summary of the associations between plasma biomarkers and MMSE and FCSRT scores.

Discussion

We performed a study on both plasma t-Tau and NFL concentrations longitudinally assessed in a monocentric cohort of cognitively normal individuals with SMC. We found that both plasma t-Tau and NFL concentrations increased over time in our preclinical population. Women had a higher increase of plasma t-Tau concentrations over time compared to men. A positive interaction between female sex and aging to determine a longitudinal increase of t-Tau was also observed. To our knowledge, no other studies reported a significant association between plasma t-Tau concentrations and sex though a higher concentration of tau in CSF of females with AD was reported compared to men [36]. This may depend on differences in sex hormones with a suggested protective role of testosterone against the

^aDependent variable: NFL (pg/mL)^bDependent variable: t-Tau (pg/mL)

hyperphosphorylation of tau [36]. Indeed, it is well-known that AD is more prevalent in females than males [37]. We hypothesize that, in our sample, females with SMC showing increased plasma t-Tau concentrations might more probably progress to AD compared to males. These findings indicated that sex-specific reference values may be considered for plasma t-Tau biomarker. By contrast, we showed that sex did not impact plasma NFL concentrations. Indeed, Mattsson and colleagues did not report any sex association in a large cohort including prodromal and AD participants, while two other studies showed an association with men and women, respectively [11, 38]. Although only in CSF, NFL concentrations were higher in men than women in a large meta-analysis of healthy controls and several neurodegenerative diseases including AD [39]. Finally, the association between plasma NFL concentrations and sex remained uncertain and should be elucidated by further longitudinal studies [3, 10].

Age impacted plasma NFL concentrations over time and was associated with plasma NFL. This finding confirms the well-known relationship between aging and NFL [5, 40, 41], though not reported in some diagnostic categories (e.g., multiple sclerosis and Creutzfeldt Jacob disease) [39, 41]. Aging and relative subclinical cerebrovascular alterations per se convey to a subtle neuronal damage and, consequently, the release of axonal byproducts, such as NFL, into body fluids [29, 41, 42]. The relationship between plasma NFL increase and age should be clarified in future studies. Finally, we did not exclude that a high impact of age on plasma NFL concentrations might mask a potential sex effect in our relatively small

size cohort. By contrast, plasma t-Tau does not seem to be strictly related to age. However, the positive interaction between female sex and aging, which indicates a longitudinal increase of t-Tau in males, should be further investigated.

Results obtained for SMC individuals did not suggest the presence of higher concentrations of both plasma NFL and t-Tau in *APOE* $\epsilon 4$ carriers than in non-carriers. This finding is in line with previous studies that did not indicate significant differences between *APOE* $\epsilon 4$ carriers and non-carriers in terms of plasma NFL concentrations [5, 40]. On the other hand, no association of plasma t-Tau with *APOE* $\epsilon 4$ carrier status assessment was shown [3].

The PLS analysis confirmed that age was associated with baseline plasma NFL, whereas female sex with baseline plasma t-Tau concentrations. Additionally, plasma vitamin B12 deficiency was related to baseline plasma t-Tau concentrations. This last finding is of particular clinical relevance and further studies are needed to investigate the potential interaction of t-Tau and vitamin B12 concentrations in blood. A further independent study may check this finding out verifying if this result holds true. In case, a trial with vitamin B12 dietary

supplement may be proposed for preclinical individuals with SMC followed with serial plasma t-Tau measurements.

Plasma NFL concentrations weakly correlated with cortical amyloid load deposition at baseline. Plasma NFL was also associated to increased cortical amyloid deposition, at 2-year follow-up, in the left posterior cingulate cortex and bilateral inferior parietal cortex. Interestingly, these areas are part of the default mode network that is functionally impaired in AD [43, 44]. Our analysis indicated an effect of high baseline plasma NFL concentrations on the deposition of amyloid plaques in the brain in a population with SMC. In addition, NFL was significantly higher in amyloid-PET-positive *APOE* $\epsilon 4$ + allele carriers compared to the $\epsilon 4$ − ones at 3 years of follow-up. However, our analysis did not distinguish SMC converters to MCI or dementia from non-converters. In a previous investigation on SMC individuals, only a trend of higher plasma NFL concentrations was described in amyloid-PET-positive SMC participants versus amyloid-PET-negative ones [16]. Other studies evaluating the more advanced prodromal and dementia stages of AD did not demonstrate any association between cerebral amyloid load and plasma NFL concentrations [3, 45].

Finally, the relationship between plasma NFL concentrations and cortical amyloid deposition should be further elucidated.

We demonstrated a cross-sectional and longitudinal association between plasma NFL and t-Tau concentrations. Moreover, the rate of increase of the two plasma biomarkers was related. There is only one previous longitudinal study reporting an association between plasma NFL and t-Tau in a pooled cohort of AD, MCI, and cognitively healthy controls [3]. This suggests that both biomarkers may reflect common neurodegenerative mechanisms in preclinical individuals with SMC.

In line with other studies [5], we found a strong correlation between plasma and CSF NFL concentrations in a subset sample of our SMC individuals [5]. The strict association between plasma and CSF NFL concentrations suggests that NFL alterations in peripheral fluids mirror those occurring in the central nervous system [46].

Baseline plasma NFL concentrations were associated with a 3-year follow-up decline of MMSE score. Our findings are partially in line with those of other studies on prodromal AD and AD dementia [3, 10, 11, 45, 47, 48] and with a study on preclinical AD individuals [16]. The rate of change of t-Tau, but not of NFL, was associated with a decrease in MMSE score at three-year follow-up. The use of serial plasma biomarker measurements and the rate of change of concentrations over time may be more reliable than absolute values, at a single time point, in differentiating patients with neurodegenerative diseases from controls [47]. In this regard, a recent study confirmed that the rate plasma t-Tau increase may be predictive of the dementia development and be adopted as a biomarker for risk stratification [13].

Finally, the lack of associations of NFL and t-Tau with a decrease in FCSRT score over time here reported is possibly due to the relative short length of follow-up and the low rate of conversion in our SMC population ($N = 6$ persons, 2%). Therefore, our results on cognitive decline should be cautiously considered as a preliminary.

Limitations of study

Our study presents some caveats. First, the low number of converters (SMC-MCI and SMC-dementia) does not allow any definitive conclusions on the role of plasma NFL and t-Tau in predicting cognitive worsening over time in preclinical individuals with SMC. Furthermore, we miss some sample collection along the time points, and we lack imaging data regarding brain metabolism and atrophy. Potential effects of genetic polymorphisms other than *APOE ε4* allele on modifications of plasma NFL and t-Tau concentrations could not be ruled out. The t-Tau assay does not have a good linearity and

parallelism and our results need to be confirmed in further investigations.

Conclusion and future direction

We reported significantly increased concentrations of plasma t-Tau in female sex and the potential association of plasma vitamin B12 deficiency with plasma t-Tau concentrations. We confirmed the significant association of plasma NFL concentrations with age and the correlation with its CSF concentrations. It was a potential predictor of longitudinal cerebral amyloid deposition in specific brain areas associated with AD pathophysiology. Rate of changes of plasma t-Tau may predict longitudinal worsening of cognition in SMC individuals. We also supported previous results reporting no association between plasma NFL and t-Tau with *APOE ε4* allele. In this regard, age, sex, and *APOE ε4* allele combined with plasma NFL and t-Tau may be used to establish a risk stratification score integrating different information on the development of dementia.

In light of our findings, we believe that the impact of biological variables needs to be critically assessed in the biomarker discovery and development process for AD diagnosis [49]. Moreover, our results should not be generalizable to other more specific settings (e.g., clinical population studies), different geographies, and ethnic groups.

Exploring the impact of these biological variables on the concentrations and longitudinal trajectories of plasma NFL and t-Tau in cognitively normal individuals, independently of their stability or their development of cognitive decline over time, is crucial to define the potential role of plasma NFL and t-Tau as diagnostic, prognostic, and theragnostic biomarkers. Importantly, our study also suggested that NFL and t-Tau seem not to be considerably influenced by comorbidities and vascular risk factors and remain relatively stable. Indeed, these steps will allow to better delineate their potential context-of-use for different settings, including clinical practice and pharmacological trials. In this respect, the recruitment of individuals for clinical trials will be improved using pathophysiological blood-based biomarkers detecting individuals at risk for progression and decline. We foresee the option to enter a novel era of next-generation biomarker-guided targeted therapies for AD and other neurodegenerative diseases under the paradigm of precision medicine [50].

Publisher's Note

Springer Nature remains neutral with regard to jurisdictional claims in published maps and institutional affiliations.

Ready to submit your research? Choose BMC and benefit from:

- fast, convenient online submission
- thorough peer review by experienced researchers in your field
- rapid publication on acceptance
- support for research data, including large and complex data types
- gold Open Access which fosters wider collaboration and increased citations
- maximum visibility for your research: over 100M website views per year

At BMC, research is always in progress.
