Abstract

The present work reports on a new type of V-based catalysts, namely V-substituted hydroxyapatites, and the influence of the synthesis conditions on their catalytic performance in the oxidative dehydrogenation of propane (ODHP) reaction. V_x -substituted hydroxyapatite materials prepared with the periodic addition of ammonia during the maturation step (V_x -HAp-pH-per) were shown to exhibit a Ca₄V₄O₁₄ phase in addition to the V-substituted hydroxyapatite phase for *x* greater than or equal to 3.5. TEM characterization of the biphasic samples allowed us to demonstrate that the Ca₄V₄O₁₄ phase was grown epitaxially on the V_x-HAp nanorods. The close intimacy between the two phases was confirmed by NMR suggesting to involvement of V⁴⁺ species. Consistently EPR data of the fresh and spent samples showed that V⁴⁺ species may be stabilized at the boundaries of these two phases. The strong promotion of the oxidative dehydrogenation reaction to propene observed from 723 K for the V₄-HAp-pH-per composition is attributed to a synergistic effect between the V_x-HAp nanorods that enable the activation of propane and the Ca₄V₄O₁₄ phase that helps the redox exchanges. This synergy may be attributed to an easier electron delocalization on the V₄O₁₄ units located at the phase's boundaries.

1. Introduction

In the context of the increasing gap between the production and the demand in propene on the world market, the catalytic oxidative dehydrogenation of propane (ODHP) reaction has been recently the subject of a renewed interest.^[1] This reaction appears as an interesting alternative for the production of propene from propane to the currently used endothermic processes such as steam cracking, fluid catalytic cracking and catalytic dehydrogenation.^[2] The main challenge for the ODHP reaction lies in the development of catalysts able to activate the C-H bond of propane at a temperature low enough to avoid its total oxidation. It is usually well accepted that highly-polymerized oxide-like catalytic species are detrimental to the control of the propene selectivity.^[3] due to rapid electronic exchanges between adjacent metal species and /or fast surface oxygen ions mobility resulting in the overoxidation of adsorbed products to CO₂.^[4] Vanadium-based systems were found among the most performant catalysts for the ODHP reaction.^[1c, 2a, 3] For most supported vanadium systems, beside the support effect,^[1b, 5] and the vanadium coordination environment,^[6] the propene formation rate per V atom (also defined as turnover frequency: TOF) has been found to depend on the vanadium surface density^[3] and to reach an optimum for intermediate surface densities,^[5c, 7] suggesting that species of limited nuclearity would be beneficial to C₃H₆ selectivity.^[2a] This motivated the design of highly-dispersed species such as single sites for heterogeneous catalysis (SSHC) through metal anchoring of an organometallic complex,^[1c, 8] or controlled incorporation in hosting structures.^[9] Typically, in BEA zeolite, the TOF of monomeric pseudo-tetrahedral V species was found to be much higher than that of polynuclear oxide-like entities present as extra-framework species in the ODHP reaction.^[9b] However, such a single-site catalytic species operates at relatively high temperature and it remains controversial whether these monomeric species, present mostly in a tetrahedral environment,^[6] correspond to the optimal organization for the active sites.^[5c] Such a concept of SSHC is in line with the concept of isolation of active sites introduced by Grasselli for bulk catalysts as one of the seven pillars governing the catalytic mild oxidation reactions.^[4] The spatial isolation of active sites from each other was postulated to be a prerequisite for the control of the selectivity in mildly oxidized products by preventing them from overoxidation.^[4, 10] For bulk catalysis, this could be successfully achieved through doping of the bulk system, as in the case of the K₂O-V₂O₅ catalyst commercialized for the selective oxidation and ammoxidation of propylene to acrolein and acrylonitrile, respectively.^[4] In other bulk systems, the uniqueness of the generated structures led to favorable designs of isolated entities. This is well illustrated by the Mg₂V₂O₇ phase that was claimed to be the active catalytic phase of the VMgO system for the ODHP reaction^[11] and for several metal transition phosphates matrices, in which Mg and P were mostly considered to be beneficial by limiting the size of the active sites made of transition metal entities. The question of the optimal size of the active sites for the control of the mild oxidation selectivity was long discussed in the case of bulk catalysts.^[12] The beneficial impact of clusters of limited size over isolated transition metal monomers in phosphate matrices was ascribed to a better control of the reducibility of the metal centers in size-limited polymeric clusters, as previously reported for propane oxidation^[13], butane oxidation to maleic anhydride^[14] and isobutyric acid oxidative dehydrogenation to methacrylic acid.^[15]

Such well-defined model bulk single phase catalysts that sometimes expose isolated and unique surface active sites, potentially made of several transition metals, can be considered as SSHC bulk catalysts.^[16] In few cases, especially for the VMgO system which is known to be active in the ODHP reaction,^[1b] multiphasic compounds were however found to be more efficient than the model Mg₂V₂O₇ single phase catalyst.^[11a, 17] In addition to the site isolation principle, phase cooperation was also identified as one of the seven pillars of oxidation catalysis.^[4] Synergistic effects may result from the formation of a new active phase upon *in situ* heating of mechanical mixtures.^[18] The nanoscale intimacy between different phases, each of them exhibiting complementary catalytic functions that cannot be incorporated into a single host structure, may also lead to cooperative effects,^[4] eventually promoting the redox exchanges,^[19] which were sometimes associated with spillover of oxygen from one phase to the other.^[20]

In a recent work, we succeeded in preparing a full range of solid solutions of $Ca_{10}(PO_4)_{6}$ - $_x(VO_4)_x(OH)_2$ (with x varying from 0 to 6) vanadium-substituted hydroxyapatites under synthesis conditions for which the pH of the medium was maintained to 9 by continuous addition of ammonia (samples referred to as V_x-HAp-pH-9).^[21] These V_x-HAp-pH-9 samples were found to dehydroxylate to $Ca_{10}(PO_4)_{6-x}(VO_4)_x(OH)_{2-y}O_y$ vanadium oxy-hydroxy-apatite solid solutions upon thermal treatment.^[22] In this series of samples, vanadium was shown to be present as highly-dispersed isolated monomeric tetrahedral species (VO₄³⁻: vanadates, Figure **1** A, left). These compounds were investigated as a model system for the ODHP reaction as they likely provide increasing amounts of isolated vanadates upon increasing the V loading.^[22] Although the surface relaxation was found to result in the prevailing exposure of Ca^{2+} species on the surface at the expense of that of vanadates, the vanadium oxy-hydroxy-apatite solid solutions formed *in situ* upon heating were found to enable propane activation. This interesting peculiarity was attributed to the intrinsic and thermally-activated proton mobility that eventually generates, *in situ*, strongly basic O²⁻ species on the oxy-hydroxy-apatite surface. Yet the selectivity in propene was found to remain rather limited and below 30% over these series of catalysts. Various pH conditions were also applied during the synthesis of the V-substituted HAp samples, with either a continuous or a periodic addition of ammonia.^[21] The series of samples prepared with a periodic addition of ammonia, referred to as V_x -HAp-pH-per (with x varying from 0 to 6), was also found to form $Ca_{10}(PO_4)_{6-x}(VO_4)_x(OH)_2$ solid solutions but only for low V contents (x < 4) compared to the V_x-HAp-pH-9 series. For higher V contents ($4 \le x$ \leq 5.22), the V_x-HAp-pH-per materials exhibited a mixture of Ca₁₀(PO₄)_{6-z}(VO₄)_z(OH)₂ (with z < x) solid solutions and Ca₂V₂O₇, whereas the Ca₂V₂O₇ sole phase was formed for x = 6 only.^[21] $Ca_2V_2O_7$ is made of V_4O_{14} tetramers in which the two edge-sharing VO₅ square pyramids are connected by a corner to an external distorted VO₄ tetrahedron. Ca₂V₂O₇ therefore exhibits a crystalline structure different from that of the Mg₂V₂O₇ magnesium pyrovanadate (2 cornersharing tetrahedra), which has been claimed as the active phase of the VMgO system.^[11a, 23] To avoid any misunderstanding in the present work between the two $Ca_2V_2O_7$ and $Mg_2V_2O_7$ crystalline structures, Ca₂V₂O₇ will be hereafter referred to as Ca₄V₄O₁₄ to account for the involvement of V_4O_{14} units (Figure 1A, right) in comparison to the V_2O_7 pyrovanadate units present in Mg₂V₂O₇. The aim of the present study is to investigate and compare the catalytic behaviors of each of the $Ca_{10}(PO_4)_{6-x}(VO_4)_x(OH)_2$ solid solutions and $Ca_4V_4O_{14}$ phases in the ODHP reaction. This will enable us to consider monomeric tetrahedral VO₄ species to tetrameric V₄O₁₄ clusters associating both tetrahedral VO₄ and VO₅ square pyramid species. The samples which exhibit both of the above-mentioned phases will also be investigated. To evaluate whether there is a cooperation between these two phases in the ODHP reaction, the catalytic performance of the V_{5.22}-HAp-pH-per sample will be compared to that of the corresponding mechanical mixture of the two phases. This approach requires the precise quantification of the proportions of the two phases present in biphasic compounds, which was achieved by Rietveld refinements together with the determination of the bulk chemical composition of the corresponding samples. The influence of the Ca₄V₄O₁₄ phase on the surface composition was investigated by XPS. The origin of the observed synergistic effect in the ODHP reaction is discussed by considering the spatial proximity of the two phases and their phase boundary which were investigated by TEM, HRTEM, hetero and homo nuclear 2D solid state NMR and X-band EPR. The reducibility of the catalysts was also investigated by considering both the characterization of selected spent catalysts by EPR and in situ Raman characterization of selected samples submitted to subsequent reductive and oxidative treatments.

Figure 1: A) Representations of the structures of the vanadium-substituted hydroxyapatite exhibiting isolated VO₄ or PO₄ tetrahedra (left) and Ca₄V₄O₁₄ with V₄O₁₄ units made of two external VO₄ tetrahedra and two central edgesharing VO₅ square pyramids (right). The selected orientation of the two projected structures along *c* and *b* axis respectively, helps identifying the tetrahedra of each structures (circled) involved in the formation of a coherent interface. **B**) Representation of an epitaxially-grown Ca₄V₄O₁₄ layer on V-substituted-HAp for the V₄-HAp-pHper sample. The coherent interface, made of distorted tetrahedra identified in the grey area, benefits from the matching between the *c* and *b* cell parameters values of the V-hydroxyapatite and Ca₄V₄O₁₄ structures (~ 6.90 and 6.89 Å, respectively). Ca, O atoms and OH groups are illustrated by blue, red and white spheres, respectively, and

the phosphate tetrahedra (or vanadate ones in the case of vanadium-substituted hydroxyapatite) are colored in green.

2. Experimental section

2.1 Sample synthesis

A series of vanadium-modified hydroxyapatite samples, with nominal compositions of the $Ca_{10}(PO_4)_{6-x}(VO_4)_x(OH)_2$ solid solutions where *x* varies from 0 to 6, was prepared according to the co-precipitation procedure previously described using an automated reactor (Optimax 1001 synthesis workstation from Mettler Toledo).^[21] A Ca(NO_3)₂ (Sigma Aldrich \geq 99.0%) aqueous solution, which pH was adjusted to 10, was heated up to 353 K. A second aqueous solution containing NH4VO₃ (Sigma Aldrich \geq 99.0%) and (NH4)H₂PO₄ (Acros, 99.9%) of appropriate concentrations was adjusted to pH 10 and added dropwise (2.2 mL min⁻¹) to the Ca(NO₃)₂ aqueous solution maintained under reflux, with a stirring rate of 400 rpm and under N₂ flow to limit the carbonation of the materials. The white suspension was then aged under stirring for 4 h with a periodic addition of 28% NH₄OH/H₂O solution to maintain the medium under basic conditions, as adapted from Ben Osman et al.^[24] The washed precipitate was dried overnight at 373 K, thermally treated under Ar (150 mL min⁻¹) up to 773 K (5 K min⁻¹) and maintained at this temperature for 90 min. Due to the pH control procedure, this series of samples will be hereafter referred to as V_x-HAp-pH-per where *x* is the molar content in vanadates.

For comparison with the V_{5.22}-HAp-pH-per sample, a sample was prepared using a similar coprecipitation procedure, except that the pH was maintained at 9 during the precipitation and aging steps by continuous addition of NH₄OH. In that case, a $Ca_{10}(VO_4)_{5.22}(PO_4)_{0.78}(OH)_2$ single phase was obtained and will be hereafter referred to as V_{5.22}-HAp-pH-9.^[21-22]

2.2 Characterizations

Laboratory X-ray diffraction (XRD) patterns were recorded with a Bruker D8 Advance diffractometer equipped with a copper source ($\lambda_{Cu-K\alpha 1} = 1.54056$ Å, $\lambda_{Cu-K\alpha 2} = 1.54439$ Å) and a LynxEye detector. XRD patterns were recorded by 0.02° steps in the 2θ range of 2θ range of 8-80°. The recorded patterns were refined using the Rietveld method^[25] as implemented in the FullProf program.^[26]

Chemical analyses were performed by inductively-coupled plasma atomic emission spectroscopy (ICP-AES, CREALINS).

XP (X-ray Photoelectron) spectra were collected on a SPECS PHOIBOS 100-5MCD photoelectron spectrometer. A monochromated Al K α (hv = 1486.6 eV) radiation source having a 300 W electron beam power was used for analysis. The emission of photoelectrons from the sample was analyzed at a takeoff angle of 90° under ultra-high vacuum conditions (1 x 10⁻⁸ Pa). Photoelectrons were collected at a pass energy of 20 eV with 0.1 eV steps for C_{1s}, O_{1s}, V_{2p}, Ca_{2p} and P_{2p} XPS core levels. After data collection, the binding energies were calibrated with respect to the binding energy of the C_{1s} peak at 284.7 eV. The peak areas were determined after subtraction of a Shirley background. The atomic ratio calculations were performed after normalization by Scofield factors. Spectrum processing was carried out using the Casa XPS software package.

After outgassing of the samples at 573 K overnight, specific surface areas were obtained by nitrogen sorption performed on a Belsorp-max apparatus and were deduced from the BET method in the $0.05 < P/P_0 < 0.3$ range.

TEM characterization was carried out at the *Plateforme de microscopie of Institut des Materiaux de Paris Centre*. Morphologic analysis at low magnification was performed using a JEOL JEM 1100 microscope operating at 100 keV electron beam. HRTEM and X-EDS for structural and chemical investigations were carried out on JEOL JEM 2100 and JEOL JEM 2011 microscopes operating at 200 kV, emitting with LaB6 tip equipped with an X-ray detector (Oxford SDD X-max 80). Micrographs were recorded on all microscopes on a 4 K camera (Gatan Orius). The samples were suspended in ethanol and dispersed with an ultrasonic bath before being rapidly deposited onto a carbone coated copper grid. In addition, two samples were also embedded in a resin, then thin ultramicrotomy sections (50-70 nm) were collected on the copper grids.

The one dimensional and two dimensional (2D) solid state Nuclear Magnetic Resonance (MAS NMR) spectra were recorded at RT using a Bruker Advance spectrometer operating in a static field of 11.7 T. The resonance frequency of ⁵¹V and ³¹P were 131.5 and 202.5 MHz, respectively. A Bruker 4 mm MAS probe was used to perform the experiments at a spinning speed of 12.5 kHz. The ⁵¹V and ³¹P chemical shifts were referenced to NH₄VO₃ and 85% H₃PO₄ aqueous solution external standards, respectively. The ⁵¹V–DP NMR spectra were recorded with a pulse duration of 1 μ s (π /8), recycle delays of 0.5 s and a scan number of 128. The ³¹P–DP NMR spectra were recorded with a pulse duration of 3.2 μ s, a recycle delay of 10 or 450 s and a scan number of 64 and 8, respectively. The ³¹P MAS saturation recovery measurements were achieved by using the pulse sequence « (d20 - P1)_n - τ_r – P1 - acquisition » with a P1 impulsion time of 2.75 μ s, a recycling delay of 15 s, and a scan number of 8, a delay d20 of 50 ms, a n value of 20 and a duration of τ_r from 50 ms to 2000 s. The SIMFIT program from TOPSPIN (Bruker) was used to determine the T1 value.

The ⁵¹V-³¹P D-HMQC (heteronuclear multiple quantum coherence)^[27] experiments were performed with rf nutation frequencies of 3 and 25 kHz for ⁵¹V and ³¹P, respectively. *SR*4²₁ was used as the recoupling sequence to re-introduce ⁵¹V-³¹P dipolar interaction with a rf field strength of 25kHz (=2*v_{rot}) during 3360 μ s. Spectra result from averaging 8192 transients and a recycle delay of 1s. The ⁵¹V-⁵¹V double-quantum single-quantum^[28] spectrum used the supercycled symmetrybased $BR2_2^1$ sequence for excitation and reconversion with $\tau_{exc} = \tau_{rec} = 888.8 \ \mu s$. The rotorsynchronized t₁ increment interval in the indirect dimension was set to 74.07 μ s (v_{rot} = 13.5 kHz). The relaxation delay was 1 s and the indirect dimension was acquired with 50 slices with 1024 transients. The rf nutation frequency was 6.25 kHz for the central-transition π and $\pi/2$ pulses. The parameter q, for unequal incremented time period (qt₁ and (1-q) t₁), was set to 0.2 and the 2D spectra have been re-scaled along F₁ to obtain the normal chemical shift values.

The EPR spectra were recorded at RT and 77 K on a JEOL FA300 computerized spectrometer working at ~9.3 GHz (X-band) and 100 kHz field modulation by applying a microwave power of 2 mW. Depending on the width and amplitude of the signal, a modulation width between 0.25 and 1 mT was applied. Fresh powdered samples (50-100 mg) were introduced into a suprasil tube (int. diameter of 4 mm) and care was taken to always keep the same height of powder in the EPR tube (~2 cm). The dedicated cell used to investigate the spent catalysts consists in a U-tube reactor, connected to an EPR tube (sealed perpendicularly to the U-tube reactor), equipped with valves that allow the transfer of the sample from the U-tube reactor to the EPR tube without exposure to ambient atmosphere. For comparison purpose, the spectra were normalized per gram of sample. The g-factors were calibrated by using solid 2,2-diphenyl-1-picrylhydrazyl (DPPH). Computer simulations of the spectra were performed using the EPRsim32 program.^[29]

In situ Raman spectra were collected using a Kaiser Optical system equipped with a charge couple detector (CCD) and a LASER with $\lambda = 785$ nm (P = 300 mW, resolution 4 cm⁻¹, accumulation time: 10 s, 30 scans per spectrum) equipped with a fiber optic Raman probe (MR Probe) using the Spectra-Tech "Collector" diffuse reflection accessory to focus the laser and collect the raman scattering in a high-temperature cell. About 30 mg of powdered sample was loaded inside the heated crucible located in this cell equipped with appropriate gas inlet and

outlet connections as to pass the gas flow (30 mL min⁻¹ of $H_2(5\%)/Ar$ or $O_2(2.5\%)/Ar$) through the sample.

2.3 ODHP reaction

Prior to the catalytic runs, the samples (0.10 g unless stated otherwise) were heated in O₂ (2.1%)–He mixture (11.75 mL_{NTP} min⁻¹) at 773 K (2 K min⁻¹) for 3 h. The temperature was then decreased to 673 K.

The C₃H₈ ODH experiments were carried out in a U-type quartz reactor (10 mm i.d.). The samples were held on a plug of quartz wool, and the temperature was controlled by a Eurotherm 2408 temperature controller using a K-type thermocouple. Reactant gases (Air Liquide, used as received) were fed from independent mass flow controllers (Brooks 5850 TR and Bronkhorst F-201CV-200-RAD-11-V). Unless stated otherwise, the catalyst was typically contacted with the reaction mixture at 673 K and the temperature was increased by steps of 25 K (5 K min⁻¹) up to 773 K for about 1 h 30 at each reaction step at atmospheric pressure. Analysis of the composition of the reactor outflow was performed on-line using a μ -GC (Agilent, CP4900) using three different columns running in parallel. The 5A molecular sieve column (353 K, 150 kPa He, 200 ms injection time, 30 s backflush time) was used to separate H₂, O₂, CH₄ and CO. The poraplot Q column (373 K, 150 kPa He, 50 ms injection time, 6 s backflush time), was used to separate CO₂, C₂H₄, C₂H₆, H₂O, C₃H₆ and C₃H₈. The CP-SIL5 column (318 K, 150 kPa He, 50 ms injection time) was used to separate CO₃H₄O (acrolein).

The conversion of C_3H_8 (X C_3H_8) and the product selectivities (SA_i) were calculated as follows: X C_3H_8 (%) = ($\Sigma n_i [A_i] / (3 \times [C_3H_8]_{inlet})$) x 100,

 $S A_i (\%) = (n_i [A_i] / \Sigma n_i [A_i]) \times 100,$

where n_i , $[A_i]$ and $[C_3H_8]_{inlet}$ are the number of carbon atoms in the A_i products, the concentrations of the A_i products, and the inlet concentration of propane, respectively. The composition of the C_3H_8 - O_2 -He (3.5–1.0–43.1) reaction mixture was: 7.4 % C_3H_8 and 2.2 % O_2 in He with a total gas flow of 12.5 mL_{NTP} min⁻¹

The spent catalysts were characterized by EPR after reaction at 723 K. In these experiments, the samples loaded in the dedicated cell reactor (see above) were flushed under helium at 723 K before being kept under He (using the closing valves of the reactor) and rapidly cooled down to RT under static conditions.

Under the present experimental conditions, it was checked that the reactor did not contribute to the transformation of C_3H_8 to a significant extent at 773 K and that both C_3H_8 and O_2 conversions measured at 723 K varied proportionally to the amount of catalyst loaded in the reactor, indicating the absence of external limitations. The carbon balance was found to be above 98 %.

3. Results

3.1 Structural and surface characterizations

Earlier characterization of the V_x-HAp-pH-per series,^[21] by XRD, and ³¹P and ⁵¹V NMR spectroscopy showed the presence of a single $Ca_{10}(PO_4)_{6-x}(VO_4)_x(OH)_2$) vanadium hydroxyapatite solid solution for the materials with x < 4, in which the vanadate groups substitute the phosphate ones in the apatite framework (**Figure 1a**). For higher vanadium contents ($x \ge 4$), new diffraction peaks around 28-30.5° assigned to the Ca₄V₄O₁₄ phase^[23b] (**Figure 2**) were found to grow at the expense of those related to HAp. This results eventually in the formation of the pure Ca₄V₄O₁₄ phase for the V₆-HAp-pH-per sample, whereas a mixture

of Ca₄V₄O₁₄ and of the vanadium hydroxyapatite solid solution ((Ca₁₀(PO₄)_{6-y}(VO₄)_yOH)₂ with y < x) phases are obtained for V₄- and V_{5.22}-HAp-pH-per samples (Figure 2). As reported previously, Ca₄V₄O₁₄ formation is favored at high vanadium content due to the predominant speciation of polymeric vanadium species in solution under such high pH conditions.^[5b, 21] The crystalline compositions could be extracted from the Rietveld refinements^[25-26] (Figure 2) and the weight loading in Ca₄V₄O₁₄ was found to increase (5, 34 and 100 wt %) as x increased (4, 5.22 and 6), respectively (Table 1). The molar ratios deduced from Rietveld refinements regarding these samples (Table 1) allowed us to estimate the associated y values, assuming that stoichiometric vanadium-substituted hydroxyapatites were formed (Table 1). This table also shows that the Ca/(P+V) ratios determined by ICP are lower than that expected for stoichiometric V_x-HAP solid solutions (nominal Ca/(P+V) =1.67). For samples with $x \ge 4$, these differences can be mainly attributed to the presence of the Ca₄V₄O₁₄ crystalline phase, as shown by XRD (Figure 2) and Rietveld analysis (Table 1). These differences in Ca/(P+V) ratios may also be attributed to the formation of non-stoichiometric V_x -HAp-pH-per materials under the particular conditions used for their synthesis for which the addition of ammonia was done periodically during the aging step^[21, 30] and/or the existence of a minor fraction of amorphous material.

The surface composition determined by X-Ray photoelectron spectrometry shows that the Ca/(P+V) molar ratios of the V_x-HAp-pH-per series of samples are always significantly higher than those of the bulk composition determined by ICP analyses (**Table 1**). Such a finding has already been observed for the pure vanadium-substituted hydroxyapatite solid solution and was accounted for the involvement of Ca-rich terminations of the hydroxyapatite phase.^[22] This effect is the more pronounced as the Ca₄V₄O₁₄ fraction becomes predominant (x = 5.22 and 6), which suggests that Ca terminations should be favored also in the lamellar structure of Ca₄V₄O₁₄.^[21, 23b] Similarly, the higher surface P/V molar ratios (XPS) compared to those found

for the bulk (ICP) in **Table 1** indicates that the prepared materials exhibit V-deficient surfaces.^[22]

The slightly higher V_{2p} binding energy obtained for V₆-HAp-pH-per compared to the other samples (517.2 *vs* 516.9 eV) (**Table 1**) is attributed to a V surface environment in Ca₄V₄O₁₄ different from that found in the biphasic systems. Such binding energies indicate that vanadium is mostly present as V⁵⁺, even though the presence of a very small shoulder at 516.2 eV observable for the V_x-HAp-pH-per materials with $3 < x \le 6$ (not shown) may be indicative of the presence of a low amount of surface V⁴⁺ species. Note that the formation of Ca₄V₄O₁₄ upon heating a CaO-V₂O₅ mixture at 1723 K was reported to exhibit up to 36% of surface V as V⁴⁺ species.^[31]

Figure 2: Rietveld refinements of the X-ray diffraction patterns of a) V₄-HAp-pH-per (Bragg R-factor = 3.43%, $\chi^2 = 1.51$), b) V_{5.22}-HAp-pH-per (Bragg R-factor = 3.37%, $\chi^2 = 1.69$) and c) V₆-HAp-pH-per (Bragg R-factor = 4.42%, $\chi^2 = 1.71$). The red crosses, black and green continuous lines represent the observed, calculated and difference patterns, respectively. Vertical blue tick marks represent the Bragg reflections of Hap (1st row) and of Ca₄V₄O₁₄ (2nd row), the latter being observed as a pure phase in c).

Table 1: Phase compositions deduced from Rietveld refinements, comparison of the bulk nominal Ca/(P+V) and P/V molar ratios with those estimated from the Rietveld refinements and determined experimentally by ICP (bulk) and XPS (surface), and V_{2p} binding energy within the V_x -HAp-pH-per series

	Rietveld Composition		Ca/(P+V) molar ratio			P/V molar ratio				V _{2p} binding

3.2 Interface structure

3.2.1 Electronic microscopy

The formation of the pure Ca₄V₄O₁₄ phase for V₆-HAp-pH-per results in the presence of large particles (≥ 200 nm, Figure 3a), which is consistent with the very low specific surface area measured for this sample (Table S1). The EDX Ca/V molar ratio found to be close to 1 for this sample is also consistent with the presence of the Ca₄V₄O₁₄ phase (Table S1). It must be recalled that the reliability of the EDX analysis for the estimation of the bulk composition of the samples was ascertained for $V_{5,22}$ -HAp-pH-9, which exhibited a Ca/(P+V) EDX ratio (1.68) in good agreement with that obtained by ICP (1.67).^[21] Even though very few large particles exhibiting a Ca/V EDX ratio of about 0.92 are still visible for the biphasic V_{5.22}-HAp-pH-per sample (Figure 3b), this sample mainly shows the presence of rod-shaped particles. Such elongated rods are typical of hydroxyapatites and vanadium-substituted hydroxyapatites (S1, Figure S1). In contrast to what can be observed for HAp (Figure S1a) and V₆-HAp-pH-9 (Figure S1b), higher magnification micrographs show that the rods of the V_{5.22}-, V_{4.5}-, V₄₋ and V_{3.5}-HAp-pH-per samples appear to be encapsulated, at least partly, by an external layer (Figures 3c-f). The Ca/V ratios estimated by EDX were found to be consistent with those estimated from the Rietveld analyses for V₄-, V_{5.22}- and V₆- HAp-pH-per samples (S1 Table S1). The comparison of Figures 3c-f suggests that the thickness of the external layer is heterogeneous (see Figure 3e for V₄-HAp-pH-per). This is supported by the partial encapsulation of the rods deduced from complementary TEM examination of ultramicrotome sections showing areas with unencapsulated terminations for rod particles of V₄- and V_{5.22}-HAp-pH-per (Figure S2).

Figure 3: TEM micrographs of a) V_6 -HAp-pH-per, b) and c) $V_{5.22}$ -HAp-pH-per d) $V_{4.5}$ -HAp-pH-per, e) V_4 -HAp-pH-per, and f) $V_{3.5}$ -HAp-pH-per samples.

The coated rods were further studied by HRTEM. The presence of an inter-reticular distance of 2.63 Å is characteristic of the apatite structure ([202] plane), as illustrated in the case of the V₄-HAp-pH-per sample and the related Fourier transform reported in the top inset of **Figure 4**. The external layer was found to be difficult to characterize due to its degradation under the electron beam, except in the case of the V₄-HAp-pH-per sample. Despite its very low thickness the crystalline structure of the external could be revealed by the observation of the characteristic inter-reticular distance 2.73 Å (Fourier transform in the bottom inset of **Figure 4**) that can be attributed to the [012], [201] or [2-21] planes of Ca₄V₄O₁₄.^[23b] In addition, angles of 8.1 and 5.6° are measured between the horizontal axis of the Fourier transforms and the series of planes typical of the HAp and Ca₄V₄O₁₄ structures, respectively. This corresponds to a disorientation angle between the two series of planes of 2.5°. Such a low value is indicative of the formation of a coherent interface leading to an epitaxial growth of the Ca₄V₄O₁₄ phase onto the V₄-HAp rods (**Figure 1B**).

The agreement found between the Ca/P ratios estimated by EDX and Rietveld analysis on $V_{5.22}$ -HAp-pH-per (**Table S1**) provides support for a coating of the V-HAp rods by the Ca₄V₄O₁₄

phase. Despite the absence of XRD diffraction peaks related to $Ca_4V_4O_{14}$ for $V_{3.5}$ -HAp-pH-per (not shown), the coating of the V-HAp rods by an amorphous $Ca_4V_4O_{14}$ phase (**Figure 3 f**) is further supported by the lower Ca/V EDX ratio (2.50, **Table S1**) compared to that expected for the $Ca_{10}(PO_4)_{2.5}(VO_4)_{3.5}(OH)_2$ solid solution (2.86, **Table S1**).

Figure 4: HRTEM micrograph of V₄-HAp-pH-per sample showing partially-coated rods. The top and bottom insets correspond to the Fourier Transforms recorded for the rod and its surface coating, respectively. The interreticular distances measured for each areas and the disorientation angle of 2.5° between the two series of characteristic diffraction planes of the two phases is indicative of an epitaxial growth of the Ca₄V₄O₁₄ phase onto the V-HAp rods.

3.2.2 Solid state NMR spectroscopy

The spatial intimacy between the two crystalline phases revealed by TEM (**Figures 3** and **4**) was investigated by solid state NMR by probing the local spatial proximity between the various V and P species. For the sake of a qualitative comparison, the intensity normalized ³¹P-DP NMR spectra are reported in **Figure 5 a.** The typical narrow phosphate resonance peak observed at 2.8 ppm for V₀-HAp-pH-per,^[32] is found to shift progressively to higher δ_{31P} chemical shifts and to broaden as the phosphorus content decreases. These observations are

consistent with the formation of a $Ca_{10}(PO_4)_{6-y}(VO_4)_y(OH)_2$ solid solution and the progressive modification of the environment of phosphates.^[21] However, close examination of the spectra recorded with a repetition time of 10 s (repetition time usually used for qualitative comparison of ³¹P species) without intensity normalization (Figure 5 b) reveals that the area of the related ³¹P signals increases from V₀-HAp-pH-per to V_{5.22}-HAp-pH-per (100 vs 185 a.u., respectively), whereas a reverse tendency is expected with the lowering of phosphorus content. This led us to conclude that such short repetition time conditions should not be applied for quantitative comparisons due to the involvement of significantly different relaxation times (T1) along the samples under study. From the saturation recovery sequence, irrespectively of their preparation routes (pH control procedures),^[21] all of the samples associated with single phase vanadium hydroxyapatite solid solutions, *i.e.* V_x -HAp-pH-per (x = 0, 1.38) and $V_{5.22}$ -HAp-pH-9, exhibit similar curves (Figure 6). Their associated relaxation times deduced from the curve fitting processing agree with those usually reported for biological hydroxyapatites^[33] (~300 s) (Table 2). In contrast, for the biphasic samples made of particles exhibiting rod-like particles encapsulated by an irregular Ca₄V₄O₁₄ layer (V_x-HAp-pH-per, x = 3.5, 4 and 5.22), a very different behavior is observed (Figure 6). The curve fitting of these data (with two components for V_{5.22}-HAp-pH-per) shows that the relaxation times are about twice as low for V_{3.5}- and V₄-HAp-pH-per, and even much lower for V_{5.22}-HAp-pH-per, compared to the non- and lowlyloaded V_x-HAp-pH-per (x = 0, 1.38) samples and V_{5.22}-HAp-pH-9 (**Table 2**). In the case of the mechanical mixture, which mimics the composition of the V_{5.22}-HAp-pH-per biphasic compound, the corresponding relaxation time (287 s) was found to be quite close to those estimated for the single-phase solid solutions (Table 2). Hence, the decrease in relaxation time can only be observed for biphasic compounds exhibiting peculiar intimacy between the two phases, as corroborated by HRTEM micrographs (Figures 3 and 4). This clearly shows that this peculiar interface between the two phases must influence the NMR signal of phosphorus of the apatite phase.

Figure 5: ³¹P-DP NMR spectra of the V_x-HAp-pH-per series a) with intensity normalization achieved using the V₀-HAp-pH-per sample as a reference, b) without normalization with a repetition time of 10 s.

Figure 6: Experimental data (circles) taken from the saturation recovery sequence for pure vanadium-substituted hydroxyapatite solid solutions (V_0 -HAp-pH-per, $V_{1.38}$ -HAp-pH-per and $V_{5.22}$ -HAp-pH-9), biphasic V_x -HAp-pH-per samples with rod particles encapsulated by an irregular layer ($V_{3.5}$ -HAp-pH-per, V_4 -HAp-pH-per and $V_{5.22}$ -HAp-pH-per) and a mechanical mixture ($V_{5.22}$ -HAp-pH-9 (66 wt%)+ V_6 -HAp-pH-per (34 wt %)), and their corresponding fitted traces (solid and dashed lines).

⁴ the data were fitted with two components.

⁵ mechanical mixture representative of the chemical composition of the V_{5.22}-HAp-pH-per biphasic compound.

One dimensional (1D) Heteronuclear correlations were performed in order to investigate the spatial proximity between the ⁵¹V and ³¹P nuclei. ⁵¹V-³¹P DHMQC heteronuclear multiple quantum coherence sequence is required to probe a quadripolar nucleus such as ${}^{51}V$ (spin = 7/2), close a ³¹P nucleus (spin = 1/2). Figure 7 shows a comparison of the spectra recorded with the ⁵¹V-DP and ⁵¹V-³¹P DHMQC sequences for V_{1.38}-HAp-pH-per and V_{5.22}-HAp-pH-per. For the V_{1,38}-HAp-pH-per single phase compound (Figure 7 a), a resonance peak is observed at ~ -625 ppm for ⁵¹V-³¹P DHMQC, ascribed to isolated VO₄³⁻ tetrahedra substituting the PO₄³⁻ groups in the vanadium-substituted hydroxyapatite solid solution, for both sequences.^[21] The very limited shift of the ⁵¹V contributions observed between the two experiments (4 ppm) is explained by the probe of slightly different environments: the vanadium species close to the phosphorus ones (observed in the ⁵¹V-³¹P DHMQC spectrum) are detected at a slightly lower chemical shift than those surrounded by other vanadium species (also detected in the ⁵¹V-DP spectrum). Due to a higher vanadium content compared to V_{1.38}-HAp-pH-per, V_{5.22}-HAp-pHper shows a ⁵¹V signal associated with isolated vanadates in the solid solution at a higher chemical shift (- 605 ppm, ⁵¹V-DP sequence **Figure 7 b**).^[21] The slightly higher difference in ⁵¹V chemical shift observed between the two sequences for $V_{5.22}$ -HAp-pH-per compared to $V_{1,38}$ -HAp-pH-per (6 ppm against 4ppm), with -605 and -611 ppm for ⁵¹V-DP and ⁵¹V-³¹P DHMQC spectra respectively, is consistent with the increased probability for the VO4³⁻ tetrahedra to be close to another VO_4^{3-} tetrahedron in the apatite framework in V_{5 22}-HAp-pHper compared to $V_{1.38}$ -HAp-pH-per. More interesting is the presence of a signal at lower chemical shift (- 574 ppm, Figure 7 b) observed in the ⁵¹V DP spectrum of V_{5.22}-HAp-pH-per, which can be ascribed to the VO_4^{3-} distorted tetrahedra of the $Ca_4V_4O_{14}$ phase. The additional contribution at -540 ppm, ascribed to the VO5⁵⁻ square pyramids of Ca₄V₄O₁₄, could not be observed in these conditions as such a contribution is expected to be much broader and less intense than that at - 574 ppm, as seen in earlier studies.^[23a, 34] The absence of the signal at -574 ppm in the ⁵¹V-³¹P DHMQC spectrum of the biphasic compound (**Figure 7 b**) shows that the phosphate groups constitutive of the apatite solid solution must not be close enough to the vanadate tetrahedra of the $Ca_4V_4O_{14}$ phase and/or this approach was not sensitive enough to probe the interface between the two phases.

Figure 7: Comparison of ⁵¹V-DP and ⁵¹V-³¹P DHMQC spectra for a) V_{1.38}-HAp-pH-per and b) V_{5.22}-HAp-pH-per.

Two dimensional homonuclear ⁵¹V-⁵¹V correlations were also probed via⁵¹V DQ/SQ (double quanta/simple quanta) experiments.^[28, 35] The parameters used for such complex experiments were preliminary validated on the α -Mg₂V₂O₇ pyrovanadate compound (**supplementary information S3**). In the case of the V_{5.22}-HAp-pH-per sample, the 2D mapping within the -560 to -625 ppm range was investigated in order to probe the signals associated with VO₄³⁻ tetrahedra (~ - 605 ppm) in the apatite solid solution and the more intense signal of Ca₄V₄O₁₄ (-575 ppm) ascribed to the external distorted tetrahedra of the V₄O₁₄ entities. Only the two related autocorrelation signals located on the diagonal are observed in **Figure 8**. The absence of cross correlation signal (between the -605 and -575 ppm components) means that the V⁵⁺

species from the solid solution are not close enough to the V⁵⁺ species of the distorted tetrahedra of Ca₄V₄O₁₄. One cannot totally exclude that, despite the favorable narrowness of the related signals, the detection limit would be too low to probe the hetero and homonuclear correlations. However, it is noteworthy that the proximity between the two phases is close enough so that the presence of Ca₄V₄O₁₄ induces a modification of the relaxation time of phosphorus. This effect may also result from the involvement of paramagnetic species.^[36] Hence, the involvement of V⁴⁺ species instead of V⁵⁺ species at the interface between the two phases may account for the apparently conflicting NMR results, as such paramagnetic V⁴⁺ species are NMR silent yet likely to induce perturbations in the spectra. An EPR study was thus undertaken to investigate this particular matter.

Figure 8: ⁵¹V DQ/SQ 2D spectrum of the V_{5.22}-HAp-pH-per sample. The DP ⁵¹V 1D spectrum is reported on the top to help identification of the V species in the 2D spectrum.

3.2.3 EPR spectroscopy

Figure 9 shows representative EPR spectra recorded at 77 K on highly-loaded V_x -HAp samples. In the case of the V_{5.22}-HAp-pH-9 sample, which has been shown to be a single solidsolution Ca₁₀(PO₄)_{0.78}(VO₄)_{5.22}(OH)₂ phase, ^[21] spectrum **a** of **Figure 9** shows a multiplet signal of weak intensity, which can be attributed to the presence of isolated V^{4+} species. Similar EPR signals, albeit of higher intensity, were reported by Boechat et al. upon H₂ thermal treatment of $Ca_{10}(PO_4)_{6-x}(VO_4)_x(OH)_2$ materials.^[37]. The spectrum recorded on V₆-HAp-pH-per (pure Ca₄V₄O₁₄ compound, spectrum **b** of **Figure 9**) appears to be much more intense and complex. This very atypical spectrum exhibits both hyperfine and remarkably defined superhyperfine structures. The hyperfine splitting is characteristic of the interaction between the 3d¹ electron and the ⁵¹V (I = 7/2) nucleus of a V⁴⁺ species (**Table 3**). The superhyperfine sub-structure, presenting an unprecedented resolution (A_{SHF,//} ~ 2 mT and A_{SHF, \perp} ~ 1 mT), can be tentatively decomposed into two long-distance interactions: a first one between the 3d¹ electron and a neighboring V^{5+} nucleus (I = 7/2) and a second one, of comparable magnitude, with a neighboring nucleus with I = 1/2, such as H. Comparison of the V₆-HAp-pH-per spectra recorded at 77 K and at RT (S4, Figure S4) shows that both spectra are similar in shape, whereas the spectrum recorded at RT was found to be about 4 times less intense than that recorded at 77 K. This difference in intensity that is in line with the Curie law dependence of the EPR signals discards the involvement of more than one V⁴⁺ center and indicates that this V⁴⁺ species does not exhibit a tetrahedral environment.^[38] Yet, this rather suggests its localization in the square pyramid of the V₄O₁₄ unit. The higher intensity of spectrum **b** compared to spectrum a in Figure 9 is in line with the computational calculations of Cheng et al. concluding to a better stabilization of V⁴⁺ species in dimeric square pyramids compared to isolated tetrahedra supported on anatase.^[6]

Figure 9: EPR spectra recorded at 77K for **a**) $V_{5.22}$ -HAp-pH-9, **b**) V_6 -HAp-pH-per, **c**) $V_{5.22}$ -HAp-pH-per **d**) V_4 -HAp-pH-per and **e**) spent V_4 -HAp-pH-per catalysts. The signals labeled with * and \circ symbols correspond to the two distinct signals of V^{4+} species exhibiting superfine splitting. The former signals exhibit similar characteristics to those observed in spectrum **a** (except the loss of the superhyperfine structures).

The comparison of materials with similar V loadings exhibiting either a single V-HAp solid solution (V_{5.22}-HAp-pH-9, spectrum (a) of Figure 9) or a biphasic composition (V-HAp solid solution and C₄V₄O₁₄, V_{5.22}-HAp-pH-per, spectrum (c) of Figure 9) shows that the intensity of the EPR signal not only is more than one order of magnitude higher for the latter sample compared to the former one but the shape of the signal also becomes much more complex. The spectrum recorded on the biphasic V₄-HAp-pH-per sample (spectrum (\mathbf{d}) of Figure 9) was found to be qualitatively similar to that recorded on $V_{5.22}$ -HAp-pH-per (spectrum (c) of Figure 9). The complexity of the central signal region of the latter spectra may be assigned to the superimposition of two signals due to isolated V^{4+} species. Interestingly, as illustrated in **Figure** 9, among the two V^{4+} species exhibiting superfine splitting in the biphasic compounds (spectra (c) and (d)), the one associated with $g_{\parallel} = 1.920$ (Table 3) with characteristic signals labelled with a * agrees with that observed for the Ca₄V₄O₁₄ compound (spectrum (b)). The corresponding signal (* label) is thus ascribed to V⁴⁺ species located in the square pyramid of the V_4O_{14} units of $Ca_4V_4O_{14}$. The loss of the superhyperfine structures observed for $Ca_4V_4O_{14}$. in the biphasic compounds (spectra (c) and (d) of Figure 9) clearly indicates the occurrence of some geometrical distortion of V_4O_{14} unit in the latter samples. The second V^{4+} species observed in the biphasic samples ($g_{\parallel} = 1.860$, characteristic signals labelled with a \circ in spectra (c) and (d) of Figure 9, which was not observable in the spectrum (b) of Figure 9, must be located in a different environment. According to Figure 10, both * and o signals are observed at RT for V_{5.22}-HAp-pH-per. Although the intensity of both signals was found to increase as the temperature decreases, the increase in the intensity of the o signal was the more pronounced. This indicates that the corresponding V^{4+} species exhibits a shorter relaxation time compared to that of the V^{4+} species located in the-square pyramidal environment of the V_4O_{14} unit (* signals). Simulation of the g and A coupling constant values associated with these two paramagnetic species are listed in **Table 3** for the $V_{5,22}$ -HAp-pH-per sample (similar results were obtained for V₄-HAp-pH-per, not shown). The parallel components g_{\parallel} and A_{\parallel} could be more accurately modelled than the perpendicular ones and were reported in Figure 10. Table 3 shows that the EPR features obtained for the first species are quite close to those estimated for Ca₄V₄O₁₄ (without superhyperfine structure), confirming its assignment to V⁴⁺ ions located in square pyramids. According to earlier literature EPR studies (Table S5) dealing with V^{4+} located either in tetrahedral or in distorted octahedra,^[38c, 39] the combination of the EPR parameters estimated for the second V^{4+} species (**Table 3**) appears to be quite unusual with i) a strong axial deformation, (ii) a low g_{ll} value (1.86) and (iii) a high value for A_{ll} component. The g_{\parallel} value found in the present study is close to those reported for V^{4+} species in a tetrahedral environment, though that of g_{\perp} is lower than the values classically reported for a tetrahedral geometry and that of $A_{\!\perp}$ is intermediate between the two sets of values reported earlier for $V^{4\scriptscriptstyle+}$ species in tetrahedral or distorted octahedral environments (Table S5). Moreover, the relaxation time is also estimated to be intermediate between those usually found for those environments, being responsible for the large increase in the signal intensity at low temperature and the fact that the signal remains observable at RT (Figure 10). Hence, all of these EPR features associated with the second hyperfine structure (o signals) indicate that these V⁴⁺ species must be present as strongly distorted tetrahedra. Given that such a species could only be observed in the biphasic compounds, it is inferred that such a strongly distorted tetrahedron results from the formation of a coherent interface between the V-substituted hydroxyapatite solid solution (rods in Figure 3d-f) and the Ca₄V₄O₁₄ phase (external layer in Figure 3d-f). This coherent interface could thus result from the epitaxial growth of V_4O_{14} units onto isolated VO_4^{3-} tetrahedra also belonging to the V-substituted hydroxyapatite solid solution (Figure 1A, 1B). As depicted in Figure 1B, such an epitaxial growth is made possible due to the very good matching between the c and b cell parameters of the vanadium-substituted hydroxyapatite and $Ca_4V_4O_{14}$ structures, ~6.90 and 6.89 Å, respectively.^[21, 23b] As indicated by EPR, such an epitaxial growth favors the formation of an additional defective V^{4+} in interfacial highly-distorted tetrahedron and must also be responsible for some distortion of the square pyramid resulting in the loss of the superhyperfine structure that could be observed in the pure Ca₄V₄O₁₄ compound.

Figure 10: EPR spectra of V_{5.22}-HAp-pH-per recorded at RT and 77 K. * and \circ symbols show the positions of the hyperfine structures (A_{||} only) of the two V⁴⁺ species.

pH-per and V_{5.22}-HAp-pH-per spectra.

3.3 ODHP reaction

3.3.1 V_x-HAp-pH-per samples

The catalytic behavior of the V_x-HAp-pH-per samples, whose specific surface areas are listed in **Table 4**, has been evaluated for the ODHP reaction. The evolution of the concentrations of the C₃H₈, O₂, CO_x (CO + CO₂) and C₃H₆ as a function of the reaction temperature and time on stream recorded on the V_x-HAp-pH-per series of catalysts were found to be similar (not shown) to that reported in our earlier study on V_{5.22}-HAp-pH-9 in the same operating conditions (7.4% C₃H₈, 2.2% O₂ in He, 12.5 mL_{NTP} min⁻¹ total flow, W/F= 8 mg min mL_{NTP}⁻¹).^[22] Traces of ethylene, acetone/propanal and acrolein were also recorded. As was the case for the V_x-HAppH-9 series, traces of hydrogen were also observed.^[22] Overall, the conversions of C₃H₈ and O₂ were found to remain essentially constant with time on stream.

x	0	3	3.5	4	4.5	5.22	6
Specific surface area (m ² g ⁻¹)	50	35	43	34	41	28	3

Table 4: Specific surface areas of the V_x-HAp-pH-per samples

The influence of the vanadium loading in the V_x -HAp-pH-per materials on C_3H_8 conversion and C_3H_6 selectivity are shown in **Figure 11**. The V-free sample was found to be poorly active and selective in the ODHP reaction at 723 K. The low conversion measured for the fullysubstituted sample (V₆-HAp-pH-per) is ascribed to its very low specific surface area (**Table 4**) and/or to poor intrinsic ability to activate C₃H₈. At 723 K, C₃H₈ conversions do not differ to a significant extent from those reported earlier for the V_x -HAp-pH-9 series in similar operating conditions^[22] and are only slightly modified by the introduction of V, except for the V₄-HAppH-per sample. The C₃H₈ conversion of the latter catalyst appears to be promoted drastically by a factor of about 4 compared to that of the other samples of the series (Figure 11). This maximum of activity, which was found to be measured reproducibly on several catalytic measurements and several batches of catalyst, could definitively not be ascribed to differences in specific surface areas (Table 4) and was observed for the whole range of reaction temperatures investigated. Note that at 748 K, a more progressive decrease of the C₃H₈ conversion is observed for x higher than 4 compared to what was observed at 723 K (Figure 11). C₃H₆ selectivity increases to a much greater extent on the V_x -HAp-pH-per series (~45%, Figure 11) compared to the V_x-HAp-pH-9 series ($\sim 25\%^{[22]}$) and is found to remain essentially constant for *x* higher than or equal to 3.

Figure 11: Influence of the vanadium loading in the V_x-HAp-pH-per series on C₃H₈ conversion at 723 (\bullet , solid line) and 748 K (O, dotted line) (\bullet) and C₃H₆ selectivity (\blacktriangle) at 723 K (7.4% C₃H₈, 2.2% O₂ in He, 12.5 mL_{NTP} min⁻¹ total flow, W/F= 8mg min mL_{NTP}⁻¹).

The selectivity in propene was also found to remain stable with increasing temperature for the whole V_x -HAp-pH-per series (**Figure S6**). This peculiarity is attributed to the similar activation energies measured for the productions of C₃H₆ and CO_x (**Table S6**), which suggests that CO_x are formed from a direct route rather than from over-oxidation of propene.

Given that the VMgO system is considered as a reference for the ODHP reaction,^[11a-c] additional set of experiments were performed in oxygen rich conditions to compare the behavior of our most active V₄-HAp-pH-per sample with that of 69-VMgO catalyst exhibiting a similar V weight loading^[11a] (**S7**, **Figure S7**). It was found that the catalytic performance recorded on V₄-HAp-pH-per compares reasonably well with that reported on 69-VMgO by Siew Hew Sam et al., albeit substantially lower C₃H₆ selectivity is achieved on V₄-HAp-pH-per compared to that reported earlier on a 69-VMgO sample^[11a] (**Table S7**).

3.3.2 Synergistic effect in the ODHP reaction due to phase cooperation

When both of the vanadium-substituted hydroxyapatite and Ca₄V₄O₁₄ phases were formed simultaneously, an intimate contact was observed between them (**Figures 3 and 4**) in the V_x-HAp-pH-per series, resulting in a synergistic effect that promoted both C₃H₆ selectivity (for $x \ge 3$) and C₃H₈ conversion (for x = 4 at 723 K and from x = 4 to 5.22 at 748 K) (**Figure S7**). In contrast, a mechanical mixture mimicking the composition of the V_{5.22}-HAp-pH-per sample (**Table 1**) prepared by grinding the two V_{5.22}-HAp-pH-9 and Ca₄V₄O₁₄ (V₆-HAp-pH-per) pure phases with a 66/34 weight ratio and subsequent thermal treatment did not show any benefit on the C₃H₆ selectivity (**Figure S8**) compared to what was obtained for the V_x-HAp-pH-9 samples series.^[22]

Identified as one of the seven pillars of oxidation catalysis by Grasselli,^[4] a cooperative effect between two phases in intimate contact usually benefits from complementary catalytic functions that cannot be incorporated into a single host structure. Such a synergistic effect is typically observed in the present study as biphasic materials of the V_x-HAp-pH-per series were found to be more active and more selective in the ODHP reaction than the two phases taken separately (vanadium-substituted hydroxyapatite in the V_x-HAp-pH-9 series with isolated VO₄ tetrahedra ^[22] or Ca₄V₄O₁₄ in V₆-HAp-pH-per involving V₄O₁₄ clusters, **Figures 1A and 11**) or associated in a mechanical mixture (**Figure S8**)). **Figure 11** shows that C₃H₆ selectivity is drastically improved with the formation of Ca₄V₄O₁₄ in the V_x-HAp-pH-per series (**Figure 3**). Yet the low activity of V₆-HAp-pH-per suggests that Ca₄V₄O₁₄ does not contribute in itself to C₃H₈ activation and that C₃H₈ activation should more likely occur on the V-HAp phase.^[22] The HAp host lattice exhibits a unique structural property, which has been found to be promoted with the incorporation of vanadates, resulting in the formation of an oxy-HAp active phase, whose O²⁻ surface anions are basic enough to activate the C-H bond of propane.^[22] The observed maximum in C₃H₈ conversion (**Figure 11**) for V₄-HAp-pH-per may be attributed to the formation of a coherent interface between the V-HAp nanorods and the Ca₄V₄O₁₄ coating layer (**Figure 4**) and to an optimal balance between these two phases (V-HAp/Ca₄V₄O₁₄ = 95/5 weight ratio, **Table 1**). The amount of vanadates present in the HAp lattice is thought to be too low to efficiently promote C₃H₈ activation because of the two low V content for x < 4 and the competitive formation of the Ca₄V₄O₁₄ phase for x > 4 (**Table 1**). It must be highlighted here that the activation energy of the ODHP reaction for the production of C₃H₆ is the greatest for V₄-HAp-pH-per (155 kJ/mol) compared to those of the other samples of the V_x-HAp-pH-per series (115 – 118 kJ/mol) (**Table S6**). Based on the well-known compensation effect phenomenon in catalysis between the activation energy and the pre-exponential factor,^[40] the fact that the catalyst exhibiting the greatest activation energy also appears as the most active sample among the series may be attributed to a much greater pre-exponential factor. It must be stressed that the pre-exponential factor of the kinetic constant also includes the number of active sites.^[40] This optimum composition between the two phases on the V₄-HAp-pH-per material may therefore be attributed to an optimum composition in terms of number of active sites and/or facilitated access of the reactants to these active sites.

 C_3H_6 selectivity was found to be strongly promoted (**Figure 11**) when the isolated tetrahedral vanadates present in the vanadium-substituted hydroxyapatite nanorods are associated with minute amounts of V₄O₁₄ clusters present in the Ca₄V₄O₁₄ coating layer (**Figure 1B**. Dasireddy et al. also concluded to a beneficial influence of the formation of Ca₂V₂O₇ pyrovanadate on the olefin selectivity in the ODH of *n*-octane.^[41] Whereas too rapid redox exchanges were claimed to be responsible for over-oxidation reactions in transition metal oxide-like compounds, and isolated transition metal species were found to be too hardly reducible, ^[1c, 3-4] metal clusters of limited size (potentially isolated from each other in phosphate matrices also referring to as the concept of isolation of active sites ^[4, 10, 12]) were reported to be beneficial for a better control of the electronic exchanges in oxidation reactions.^[13-15, 42] In order to monitor the redox properties

of the Ca₄V₄O₁₄-containing samples, an *in situ* Raman investigation was carried out under successive reductive ($H_2(5\%)/Ar$) and oxidative ($O_2(2.5\%)/Ar$) atmospheres (Figure 13). The intensity of the Raman V-O bands^[21, 43] of V₄-HAp-pH-per at 423 K were found to decrease upon thermal reductive atmosphere at 623 and 723 K (without any alteration of the bandwidth). This loss of the V-O vibrators was found to be reversible as subsequent treatment at 723 K under an oxidative $(O_2(2.5\%)/Ar)$ atmosphere results in the recovery of the initial intensities of the various contributions (Figure 12). Such a removal of the lattice oxygen anions from the host structure and their recovery in an oxidizing atmosphere are important prerequisites for oxidation catalysts^[4, 44] active in the ODHP reaction.^[1a, 1b, 45] Similar behaviors were observed for all of the Ca₄V₄O₁₄-containing samples (not shown). The ability of the epitaxially-grown C₄V₄O₁₄ phase to favor redox exchanges was also confirmed by EPR as a significant increase in the intensity of the two EPR signals assigned to paramagnetic V^{4+} species could be observed in the spent biphasic catalyst (Figure 9, spectrum e). Interestingly, the relative concentration of the V^{4+} species present in external tetrahedral vanadates of interfacial V_4O_{14} units seems to be more impacted than the V^{4+} species in the square pyramids in the spent sample (Figure 9, spectrum e vs spectrum d). Yet, given the global decrease in intensity of all Raman bands (Figure 12), and the lack of operando EPR data, it remains difficult in the present study, as it is in earlier literature reports, $^{[42a, 46]}$ to formally assess whether the V_t-O-V_{spyr} oxygen species (interfacial O species located between a tetrahedron and a square pyramid, Figure 1B)) is

preferentially involved in the reduction process compared to those of the $v_0^0 v$ double

bridges associated with edge-sharing square pyramids or not. Nevertheless, this EPR study puts particular emphasis on the redox exchanges occurring at the coherent interface between the V-HAp rods and the Ca₄V₄O₁₄ overlayer (**Figure 1B**). Such an easy electron transfer occurring between adjacent vanadium species may favor the spreading of the electrons over several

vanadium species of interfacial V₄O₁₄ entities, finally making these electrons accessible for the adsorbed molecules, as discussed earlier for iron Fe₃O₁₂ trimeric clusters ^[46] present in α -Fe₃(P₂O₇)₂ active in the oxidative dehydrogenation of isobutyric acid to methacrylic acid.^[15]

detailed in the top inset under reductive (H₂(5%)/Ar) and then oxidative ($O_2(2.5\%)/Ar$) flows (30 mL min⁻¹).

4 Conclusion

 V_x -substituted hydroxyapatite materials prepared with a periodic addition of ammonia during the maturation step (V_x -HAp-pH-per) were shown to exhibit a Ca₄V₄O₁₄ phase in addition to the V-substituted hydroxyapatite phase for x value greater than or equal to 3.5. Its crystalline fraction deduced from Rietveld analysis was found to rapidly increase from 5 to 100 wt% as x increases from 4 to 6. TEM characterization of the biphasic samples allowed us to demonstrate that the Ca₄V₄O₁₄ phase was grown epitaxially on the V_x-HAp nanorods, which ensures a close intimacy between the two phases, even if encapsulation of nanorods remained partial. According to Solid State NMR, the modification of the relaxation time of phosphorus present in the V-substituted hydroxyapatite phase coated by Ca₄V₄O₁₄ strongly suggested the involvement of paramagnetic V^{4+} in the structuration of the interface. This was confirmed by EPR showing, in addition to the V^{4+} species located in the central square pyramids of the V_4O_{14} units of the Ca₄V₄O₁₄ phase, a second V^{4+} signal for biphasic compounds ascribed to V^{4+} species stabilized at the boundaries of these two phases. Compared to the other samples of the series and the fully-substituted V-HAp counterparts (V_x -HAp-pH-9^[22]), the oxidative dehydrogenation of propane to propene reaction was found to be strongly promoted as soon as 723 K over the V₄-HAp-pH-per sample. This promotion is attributed to a synergistic effect between the V_x -HAp nanorods and the Ca₄V₄O₁₄ phase providing that they are in close intimacy, which could not be achieved in a mechanical mixture. This synergy may be attributed to the combination of complementary functions of the two phases: (i) the ability to activate C_3H_8 over V-substituted oxy-hydroxy-apatite phase ^[22] and (ii) the promotion of C_3H_6 selectivity, provided by optimized redox properties of V_4O_{14} units that favor easier electron delocalization on the V₄O₁₄ units located at the phases' boundaries. This was illustrated by the modification of the fresh and spent EPR spectra of V₄-HAp-pH-per catalyst and its peculiar ability to lose and recover its network oxygen species under reductive and oxidative atmospheres, respectively, as shown by *in situ* Raman spectroscopy. The optimal catalytic ODHP performance achieved for the V₄-HAp-pH-per probably results from its optimal composition, which combines a higher fraction of C_3H_8 activation sites (V-substituted phase) and the formation of a coherent interface with the $Ca_4V_4O_{14}$ phase that would prevent C_3H_6 overoxidation. Finally, the catalytic performance of the V₄-HAp-pH-per catalyst was found to compare reasonably well with that of a VMgO reference catalyst.

Acknowledgments:

The authors thank the DIM OXYMORE program of the Région Ile-de-France for supporting the PhD work of Dr. S. Petit. The authors are grateful to C. Calers and V. Losinho from the Laboratoire de Réactivité de Surface, Sorbonne Université, for their help in the XPS measurements and the *in situ* Raman set-up, respectively.

Graphical abstract

The epitaxial growth of a $Ca_4V_4O_{14}$ phase onto vanadium-substituted hydroxyapatite (V-HAp) resulted in a synergistic effect for the oxidative dehydrogenation of propane (ODHP). Such a phase cooperation highlighted on the V₄-HAp sample is ascribed to complementary catalytic functions: i) peculiar ability of V-HAp to activate propane and ii) easier electron delocalization on the vanadium tetramers in $Ca_4V_4O_{14}$ compared to monomeric vanadates in V-HAp that is beneficial to propene selectivity.

Synergistic Effect Between Ca₄V₄O₁₄ and Vanadium-Substituted Hydroxyapatite in the Oxidative Dehydrogenation of Propane.

S1 TEM and HRTEM study of Ca₁₀(VO₄)₆(OH)₂ and Ca₁₀(VO₄)₆(OH)₂ single phases.

As already described in the case of non-substituted hydroxyapatite samples prepared under similar conditions, the hydroxyapatite particles consist of elongated rods well crystallized till their surface terminations (**Figure S1a**).^[1] Successful substitution of phosphate species by vanadate species in the HAp framework allows the preservation of a single phase, leading to a morphology similar to that found for HAp, as illustrated in **Figure S1b** for the fully-substituted vanadium sample (Ca₁₀(VO₄)₆(OH)₂ single phase) prepared with continuous addition of NH₄OH during the synthesis to maintain the precipitation medium at pH 9 (measured at 80 °C).^[2]

Figure S1a: HRTEM micrograph of $Ca_{10}(PO_4)_6(OH)_2$ illustrating a monocrystalline elongated rod. The inter fringe measured on the image (1.8 A) corresponds to [100] Hap planes.^[1]

Figure S1b: *TEM* micrograph of V₆-HAp-pH-9 exhibiting a single $Ca_{10}(VO_4)_6(OH)_2$ phase. This fully-substituted vanadium hydroxyapatite material was prepared with continuous addition of NH₄OH to maintain the precipitation medium at pH 9 (measured at 80 °C).^[2]

S3 Validation of ⁵¹V DQ/SQ sequence for α-Mg₂V₂O₇ sample

The parameters of the ⁵¹V DQ/SQ double quanta/simple quanta experiments^[3] were first optimized on a α -Mg₂V₂O₇ sample. This sample was prepared following the procedure described by Gao et al. by the citrate method with a nominal Ca/V molar ratio equal to 1. ^[4] The purity of the pyrovanadate crystalline structure was ascertained by XRD (**Figure S3 a**). This compound is built up from V₂O₇ entities (two sharing corner tetrahedra) that lead to ⁵¹V fingerprints at -551 and -607 ppm (**Figure S3 b**). **Figure S3 c** shows two autocorrelations ((V(1) and V(2)) related to the two identical vanadium species in close proximity. In addition, the cross correlation signals ((V(1)-V(1) and V(2)-V(1)) clearly show that each vanadium species is in close proximity with that of the vanadium species of the other type. This confirms that the applied NMR sequence enables the detection of V(1)-O-V(2) bridges characteristic of the pyrovanadate structure.

Figure S3: XRD pattern obtained in the 10-90° range for α -Mg₂V₂O₇ magnesium pyrovanadate compound a), related DP ⁵¹V NMR spectrum b) and ⁵¹V DQ/SQ spectrum c).

S4 Influence of temperature on EPR spectra of Ca₄V₄O₁₄ sample

Figure S4 shows that the spectra recorded at 77 K and RT are similar in shape, whereas the intensity of the spectrum recorded at RT is about 4 times lower than that recorded at 77 K. This difference in intensity is in line with the Curie law dependence of the EPR signals (intensity \propto 1/T). This Curie law is, however, not valid for 3d¹ ions such as V⁴⁺, Cr⁵⁺and Mn⁶⁺ in tetrahedral coordination (due to their very short relaxation times), which can only be detected at low temperature. ^[5] Hence, the observed changes in intensity of the signal with the temperature indicates that the V⁴⁺ species responsible for these EPR signals should be located in the square pyramids of the V₄O₁₄ units constitutive Ca₄V₄O₁₄ rather than in their external tetrahedral vanadates.

Figure S4: Comparison of the EPR spectra recorded at RT and 77 K on V₆-HAp-pH-per.

S5 Typical EPR parameters for V⁴⁺ species

Matrix	g_{\parallel} or g_z	A∥ (mT)	g_{\perp} or g_x	$A_{\perp} \text{ or } A_x$ (mT)	gy	A _y (mT)	geometry
ThSiO ₄ ^[5c]	1.84	19.1	1.99	3.6	-	-	Td ^{\$}
ThGeO4 ^[5c]	1.83	19.4	1.98	3.5	-	-	Td ^{\$}
Garnet ^[6]	1.86	17.5	1.98	3.4	-	-	Td ^{\$}
Vitrous SiO ₂ ^[7]	1.89	16.7	1.95	6.3	-	-	Td ^{\$}

Table S5: EPR features reported for V^{4+} species exhibiting low g_{\parallel} value (or related g_x in case of the orthorhombic symmetry) estimated in various materials and associated geometry for the V^{4+} ions.

^{\$} indicates that no signal was observed at RT

According to the data listed in **Table S5**, V^{4+} species can be divided into two environments: on the one hand, V^{4+} species in a tetrahedral environment (Td), that are detectable only at low temperature and on the other hand, V^{4+} species in a distorted octahedral environment (Oh) that are detectable as a broadened signal at RT.

If some of the EPR features of the 2nd multiplet detected in V_{5.22}-HAp-pH-per such as the A_{\parallel} value are found to be close to those characteristic of the first environment of V⁴⁺ species reported in earlier literature reports, the g_{\perp} value is lower than the values reported for the two environments of reference compounds. A_{\perp} is intermediate between the two sets of values obtained for each environment.

S6 Influence of reaction temperature on the catalytic performance and Activation Energies.

Upon increasing the reaction temperature, the increase in C_3H_8 conversion follows quite similar profiles for all of the V_x-HAp-pH-per samples (see representative plot for V_{5.22}-HAp-pH-per in **Figure S6**), with a marked inflection point from ~715 K, except in the case of the V₄-HAp-pHper sample. For the latter sample, a rapid increase of the conversion is observed from 673 K. For the whole V_x-HAp-pH-per series, the selectivity in propene was found to remain stable with increasing temperature.

Figure S6: Evolution of C_3H_8 (\bullet) and O_2 (×) conversions, and C_3H_6 selectivity (Δ) as a function of reaction temperature for the biphasic V₄-HAp-pH-per and V_{5.22}-HAp-pH-per catalysts, the single phase V_{5.22}-HAp-pH-9, and the mechanical mixture (66 wt% of V_{5.22}-HAp-pH-9 + 34 wt % of V₆-HAp-pH-per) (7.4% C₃H₈, 2.2% O₂ in He, 12.5 mL_{NTP} min⁻¹ total flow).

Table S6 Activation energies (E_a) for C_3H_6 and CO_x formation in the ODHP reaction (7.4% C_3H_8 , 2.2% O_2 in He, 12.5 mL_{NTP} min⁻¹ total flow) determined in the 673-823 K reaction temperature range and related r^2 linear correlation factor for the V_x -HAp-pH-per series.

*determined in the 673-723 K range

S7 Influence of the operating reactions conditions on the catalytic behavior of V₄-HAp and comparison with a VMgO reference catalyst

The catalytic behavior of the V₄-HAp-pH-per sample has been investigated in the conditions used by Siew Hew Sam et al.^[11] for a 69-VMgO catalyst exhibiting a similar V weight loading. A new set of data was obtained with a richer oxygen mixture: $C_3H_8/O_2 = 0.09$, 16.7 ml/min total flow (F) and W/F = 6 mg min ml⁻¹). Compared to our previous O₂ poor conditions (solid lines), the catalytic ODHP performance of V₄-HAp-pH-per (dashed lines, O₂-rich conditions) appears to be no longer limited by the amount of O₂ in the reacting feed (**Figure S7**). C₃H₈ conversion at 773 K was found to be promoted under these O₂-rich conditions compared to the O₂-poor conditions used in the present work (22.0 *vs* 10.5 %, respectively). In contrast, C₃H₆ selectivity was found to be much lower at 773 K (23% in O₂-rich conditions compared to 43 % in O₂-poor conditions) and to decrease moderately as the reaction temperature increased (**Figure S7**).

Figure S7: $C_3H_8(\bullet)$ and $O_2(\times)$ conversions, and C_3H_6 selectivity (Δ) of V_4 -HAp-pH-per as a function of reaction temperature, solid lines for $C_3H_8/O_2 = 3.4$, 12.5 mL_{NTP} min⁻¹ total flow, W/F = 8 mg min mL_{NTP}⁻¹ conditions, and dashed lines for $C_3H_8/O_2 = 0.09$, 16.7 ml/min total flow (F) and W/F = 6 mg min mL_{NTP}⁻¹ conditions (corresponding to the conditions applied by used by Siew Hew Sam et al^[11].

Table S7 shows that the catalytic performance recorded on V₄-HAp-pH-per compares reasonably well with that reported on 69-VMgO by Siew Hew Sam et al., albeit substantially lower C_3H_6 selectivity is achieved on V₄-HAp-pH-per compared to that reported earlier on a 69-VMgO sample .^[11]

Table S7: Comparison of the ODHP catalytic performance at 773 and 823 K for V₄-HAp-pH-per and VMgO catalysts^[11] under similar conditions ($C_3H_8/O_2 = 0.09$, 16.7 ml/min total flow et W/F = 6 mg min mL_{NTP}⁻¹).

		69-VMgO ^[11]	V ₄ -HAp-pH-per
Specific surface area (m ² /g)		11	34
V ₂ O ₅ wt (%)		66.4	67.1
V wt (%)		18.6	18.8
Reaction at 773K	C ₃ H ₈ Conversion (%)	18	22
	C ₃ H ₆ Selectivity (%)	44	23
Reaction at 823 K	C ₃ H ₈ Conversion (%)	42	38
	C ₃ H ₆ Selectivity (%)	32	23

S8 Mechanical mixture versus biphasic system: illustration of the improved ODHP catalytic performance of the V_x-HAp-pH-per samples

A mechanical mixture mimicking the composition of the V_{5.22}-HAp-pH-per sample (**Table 1**) was prepared by grinding the two V_{5.22}-HAp-pH-9 and Ca₄V₄O₁₄ (V₆-HAp-pH-per) pure phases with a 66/34 weight ratio. It was checked that the crystalline phases constitutive of the mechanical mixture were preserved after annealing at 773 K under Ar flow (150 mL min⁻¹). C₃H₈ conversion measured for the mechanical mixture at 723 K was found to be comparable to those recorded for the V_{5.22}-HAp-pH-per and V_{5.22}-HAp-pH-9 samples (**Figure S8**). The selectivity in C₃H₆ measured on V_{5.22}-HAp-pH-9 was found to be close to that recorded for the mechanical mixture but to be significantly lower than that recorded on the biphasic V_{5.22}-HAp-pH-per compound (**Figure S8**). Overall, the mechanical mixture displayed a catalytic behavior similar to that of V_{5.22}-HAp-pH-9 and much different from that of V_{5.22}-HAp-pH-per (**Figure S8**).

Figure S8: Comparison of the C_3H_8 conversion and C_3H_6 selectivity for the biphasic $V_{5,22}$ -HAp-pH-per sample, the single phase $V_{5,22}$ -HAp-pH-9 sample and the mechanical mixture of the two phases taken with the same proportions as those estimated in $V_{5,22}$ -HAp-pH-per. (7.4% C_3H_8 , 2.2% O_2 in He, 12.5 mL_{NTP} min⁻¹ total flow, W/F = 8 mg min mL⁻¹) at 723 K.
