Characterizing the mechanical properties of tissues is key for the understanding of fundamental biological processes such as morphogenesis or tumor progression. In particular, the intercellular adhesion forces, mediated by transmembrane proteins like cadherins, are expected to control the topology and viscoelastic behavior of tissues under mechanical stress. In order to understand the influence of adhesion in tissues, we use biomimetic emulsions in which droplets mimic cells and adhere to each other through specific bonds. Here, we tune both the binding energy of the adhesive inter-droplets contacts as well as the fraction of contacts that are adhesive, thereby defining a so-called adhesiveness. Our experimental results show that adhesion prevents the emergence of local order in emulsions even at high packing fractions by preventing energetically costly droplet rearrangements. By studying the deformation of droplets within packings with different average adhesiveness values, we reveal the existence of a threshold value of adhesiveness above which all droplets in a packing are deformed as adhesive ones irrespective of their local adhesive properties. We show that this critical adhesiveness coincides with the threshold for percolation of adhesive structures throughout the tissue. From a biological point of view, this indicates that only a fraction of adhesive cells would be sufficient to tune the global mechanical properties of a tissue, which would be critical during processes such as morphogenesis.

## 1 INTRODUCTION

The macroscopic response of tissues is characterized by an elastic response at short timescales and a plastic one at long timescales, during which cells undergo rearrangements [1]. Deciphering the mechanical properties of tissues will help gain a better understanding of key biological processes including morphogenesis [2], wound healing [3] or cancer invasion [4]. Indeed, previous studies showed that proper embryo development requires a precise spatiotemporal tuning of the viscoelastic properties of the tissue [2, 5]. In particular, spatiotemporal changes in material characteristics like elastic modulus, yield strength or viscosity can strongly affect morphogenetic processes like tissue spreading or body axis elongation [6–9]. In addition to the regulation of force generation in tissues, regulating material properties thus offers a mechanism for controlling morphogenesis.

At the scale of the tissue, this viscoelastic behavior depends on the physical properties of the individual cells as well as on their adhesive properties through cadherin homophilic interactions.

Moreover, cells respond to an applied force through mechanotransduction processes [10], thus providing a feedback loop between the exerted forces and the mechanical properties of the tissue. The viscoelastic response of a tissue is therefore controlled by both biochemical pathways [11–13] and biomechanical processes [14], relying on the interplay between forces at the scale of single cells [15, 16] and cell-cell adhesion [17, 18]. In order to deepen our understanding of these complex processes, it is thus important to characterize the properties of biological tissues from a materials standpoint and to decipher the role of intercellular adhesion on the tissues properties. Further, changes in tissue properties can be fast and drastic, whereby a small change in properties at the cellular scale can lead to large changes in the macroscopic properties of the tissue. Recent approaches have therefore tackled the study of tissue mechanics by using the language and tools of phase transitions to highlight potential unifying principles.

The idea that the mechanics of tissues can be understood within the framework of a jamming or a rigidity transition scenario is now widely accepted [19–23]. For inert materials, the phase behavior of particulate systems is primarily controlled by the particle or droplet volume fraction  $\rho$ . Indeed, above a critical volume fraction  $\rho_c$ , a disordered solid develops a non-zero yield stress below which the material responds elastically and above which it flows plastically [24–28]. The distance to the jamming point ( $\rho - \rho_c$ ) generically governs the mechanical response of these disordered systems [24, 26, 29–31]. Recently, the existence of a connection between jamming and geometry spanning both inert particulate systems and living systems was conjectured [22]. Like in jamming for inert particles, jamming in epithelial tissues was linked to caging by immediate neighbors, propagating force chains and cooperative cellular dynamics. For instance, *in vitro* epithelial monolayers were shown to display density-dependent glassy dynamics [32–35]. Further, a recent study argued that the zebrafish blastoderm morphogenesis is governed by a tissue rigidity phase transition which is successfully predicted by a rigidity percolation theory on the basis of the local cell connectivity network [23].

Intercellular adhesion was shown to be one of the key components of jamming in biological tissues during development, highlighting the role of adhesion on tissue rigidity [8, 23]. The maturation and strengthening of cell-cell and cell-substrate adhesions has thus been shown to lead to the jamming of amorphous configurations in confluent epithelial tissues [34]. Moreover, computational models of confluent tissues based on the active vertex model class also display rigidity transitions controlled by cellular motility properties on the one hand, and the balance between intercellular adhesion and cortical tension on the other hand [36–38]. Likewise, adhesion was shown to stabilize higher order vertices in cell tilings, which in turn is linked to the fluid-to-solid transition of the tissue [39].

However, a quantitative approach to decipher the role of adhesion on the rigidity or jamming of tissues is difficult to reach since the binding energy between cells is not readily accessible. Moreover, the topological properties of tissues cannot generically be tuned independently of other parameters. The development of computational or biomimetic

approaches is thus useful to study the role of adhesion on the structure and mechanics of biological tissues in a quantitative manner. The effect of attractive interactions in model soft matter systems has been probed experimentally and through simulations; it has been shown to drastically change the nature of the jamming transition [40–43]. For instance, normal attraction forces have been shown to stabilize structures below isostaticity in granular packings, leading to a higher compactivity [40, 44]. Furthermore, attractive emulsions have been shown to display soft gel-like elastic structures capable of sustaining stresses below isostaticity [45–48]. Finally, a recent computational model also highlighted the crucial role of tension fluctuations for tissue rigidity transitions [49], by using a framework derived from deformable particle approaches [50, 51] and explicitly introducing adhesion between the cells.

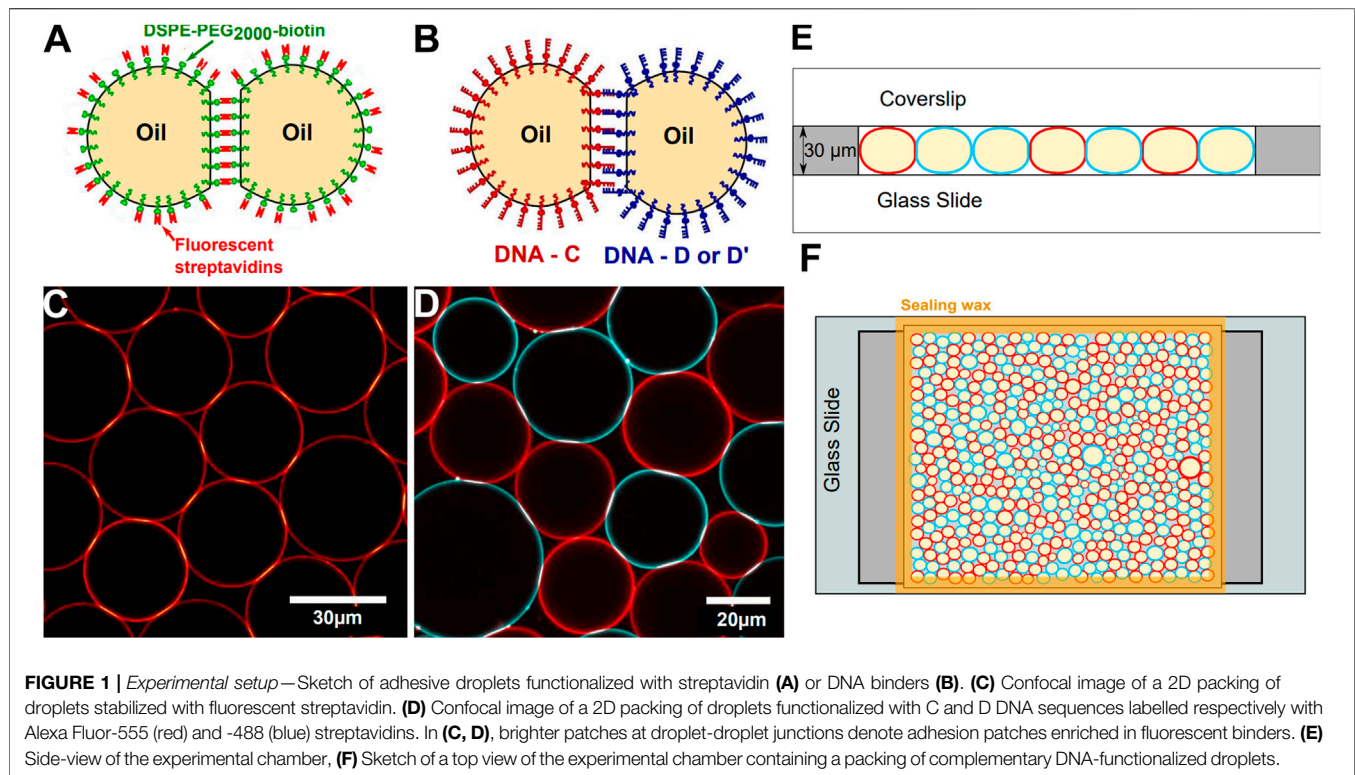

In this context, biomimetic emulsions have been developed to reproduce *in vitro* the mechanical and adhesive properties of cells in tissues [52]. These systems have shed light on the importance of compressive forces for adhesion growth within tissues and can serve as a general platform to study surface interactions through biological proteins [53]. More recently they have also probed the elasto-plastic response of tissues under mechanical stress [54] and revealed a global polarizing effect of adhesion in elongating tissues [55].

In this work, we use biomimetic emulsions in order to probe the influence of adhesion on the structure and droplet deformations in static 2D packings. We use different types of binders between the droplets, which allows us to tune not only the binding energy between the droplets, but also the number of adhesive contacts one droplet can establish with its neighbors, by varying the proportion of droplets carrying complementary binders in the emulsion. Inspired by Ref. [56], we characterize packings via their *adhesiveness*. Interestingly, we find that adhesion impairs local crystalline order even in emulsions at high packing fractions, suggesting that the presence of adhesion patches hinders emulsion remodelling, in agreement with our previous work [55]. We also show that an increased binding energy or an increased proportion of adhesive contacts in the packing lead to an increase in droplets deformation as a function of their local packing fraction. However, for any given experimental condition, i.e., one type of binder and a fixed proportion of complementary droplets, all the droplets in the packings exhibit the same deformation level independently of their local adhesive neighborhood. We relate this property to a threshold adhesiveness above which the adhesive contacts between droplets form a percolating network in the emulsion. From a biological standpoint, this suggests that tuning the adhesive properties of only a fraction of the cells could affect the global mechanical behavior of a tissue.

## 2 MATERIALS AND METHODS

### 2.1 Emulsion Preparation

An oil-in-water emulsion stabilized by Sodium Dodecyl Sulfate (SDS, Sigma Aldrich) was first prepared by emulsifying silicone

**FIGURE 1 | Experimental setup**—Sketch of adhesive droplets functionalized with streptavidin (A) or DNA binders (B). (C) Confocal image of a 2D packing of droplets stabilized with fluorescent streptavidin. (D) Confocal image of a 2D packing of droplets functionalized with C and D DNA sequences labelled respectively with Alexa Fluor-555 (red) and -488 (blue) streptavidins. In (C, D), brighter patches at droplet-droplet junctions denote adhesion patches enriched in fluorescent binders. (E) Side-view of the experimental chamber, (F) Sketch of a top view of the experimental chamber containing a packing of complementary DNA-functionalized droplets.

oil (50 cSt, Sigma Aldrich) in a 10 mM SDS solution, using a pressure emulsifier as described in [54]. The droplets stabilization was then modified by replacing the SDS with a mixture of egg L- $\alpha$ -phosphatidylcholine (EPC) lipids and DSPE-PEG(2000)-biotin lipids from Avanti Polar Lipids, at a mass ratio of 9:1, using the protocol described in [55]. At the end of this stabilization process, we obtain an emulsion of phospholipid-stabilized droplets in a 10 mM Tris, pH =  $7.2 \pm 0.2$ , 1 mM SDS buffer (referred thereafter as TS buffer) and we let it cream for the functionalization steps. The resulting droplets exhibit a mean diameter of  $33\mu\text{m}$ , with an 18% polydispersity (see **Supplementary Figure S1** for the size distribution).

### 2.1.1 Streptavidin Functionalization

In order to graft streptavidin onto the biotinylated lipids distributed on the droplets surface,  $7.1\ \mu\text{L}$  of Alexa Fluor 555-conjugated (Invitrogen) was added to  $193\ \mu\text{L}$  TS buffer and  $50\ \mu\text{L}$  of creamed biotinylated emulsion. The droplets were incubated during 1 hour at room temperature in the dark, and mixed gently once every 10 minutes in order to re-suspend the creamed emulsion. After incubation, the emulsion was washed by removing the  $200\ \mu\text{L}$  of aqueous lower phase, and subsequently adding  $200\ \mu\text{L}$  of TS buffer. This washing step is repeated 3 times to remove all unbound streptavidins that could remain in the water phase, leaving an emulsion of droplets partially covered with fluorescent streptavidin (see **Figures 1A,C**). In order to induce adhesion between the droplets, the TS buffer is replaced by a buffer supplemented in Magnesium (10 mM Tris, 1 mM SDS, 2mM  $\text{MgCl}_2$ , pH = 7.2), hereafter named TM2S buffer.

### 2.1.2 DNA Functionalization

DNA-functionalized droplets were prepared as described in [57] (see **Figures 1B,D**). DNA sequences consisted in a non-sticky biotinylated 49 base pairs (bp)-long backbone followed by an 11 bp-long sticky end. The 49 bp-long backbone can be hybridized with its complementary sequence (CS) to create a rigid double-stranded backbone. We used three complementary sticky ends:

C: 5' GGA TGA AGA TGA GCA TTA CTT TCC GTC CCG AGA GAC CTA ACT GAC ACG CTT CCC ATC GCT A Biotin-3'

D: 5' CAT CTT CAT CCA GCA TTA CTT TCC GTC CCG AGA GAC CTA ACT GAC ACG CTT CCC ATC GCT A Biotin-3'

D': Biotin-5' AGC ATT ACT TTC CGT CCC GAG AGA CCT AAC TGA CAC GCT TCC CAT CGC TAC ATC TTC ATC C 3'

CS: TAG CGA TGG GAA GCG TGT CAG TTA GGT CTC TCG GGA CGG AAA GTA ATG C.

The C sequence complements both D and D' (see slanted parts of the sequences for C/D and C/D' complementarity), as sketched in **Figure 1B**.

In order to functionalize the droplets, the DNA sequences C, D or D' were first hybridized with their complementary backbone CS: 113 pmol of CS and 113 pmol of C, D or D' were incubated together in  $200\ \mu\text{L}$  of 10 mM Tris, 1 mM SDS, and either 4 mM or 2 mM  $\text{MgCl}_2$  buffer (TM4S or TM2S buffer), for 45 min at room temperature. These proportions were chosen so that DNA strands and streptavidins are in 1:1 proportions and the streptavidin-DNA complexes occupy theoretically at most one fourth of the total droplet surface. Note that only three

experiments were carried out with the TM4S buffer. However, none of the experimental measurement differed between 2 and 4 mM MgCl<sub>2</sub>. Only the kinetics of streptavidin patches formation was impacted. Patches were formed in both cases well below the 45 min incubation before observation. Therefore, we pool together all experiments carried out with 2 and 4 mM MgCl<sub>2</sub> magnesium for a given ratio of droplets functionalized with complementary DNA strands.

Fluorescent streptavidin was then added to the DNA sequences. To do so, 7.1 μg of Alexa-488 streptavidin or Alexa-555 streptavidin at 1 mg/ml was added to the solution, and incubated during 1 h at room temperature in the dark to combine with the biotinylated end of the DNA sequences. The C sequence was associated to the Alexa-555 streptavidin and the D sequence to the Alexa-488 streptavidin, as shown in **Figure 1D**.

Finally, 207 μL of the DNA solution was added to 50 μL of creamed biotinylated droplets, and incubated for 1 hour at room temperature in the dark, with a gentle agitation every 10 min to re-suspend the droplets. These proportions were chosen so that DNA strands and streptavidin are in 1:1 proportions, and the streptavidin-DNA complexes occupy theoretically at most one fourth of the droplet total surface. After the final incubation, the droplets are rinsed with the same buffer 3 times as described above. Immediately before the experiment, the two populations of complementary DNA droplets are mixed together (see **Figure 1D**).

## 2.2 Experimental Set-Up

The experimental chamber for 2D packings is made with a glass slide and a coverslip separated by two lateral 30 μm high adhesive spacers (polymethylmethacrylate -PMMA-film, Goodfellow) as illustrated in **Figure 1E,F**. A solution of 0.5 mg/ml casein ( $\beta$ -casein from bovine milk, Sigma Aldrich) is first injected inside the chamber to prevent non-specific interactions between the droplets and the walls of the chamber and left aside for 15 min. The chamber is then rinsed with water and dried under nitrogen.

For all droplet types, the functionalized emulsion is resuspended in a water/glycerol solution (60:40 v:v), with the same composition as the desired buffer: TS buffer for non-adhesive streptavidin covered droplets, TM2S for adhesive streptavidin droplets, TM4S or TM2S for adhesive DNA droplets. The use of glycerol in the continuous phase ensures that the optical index of the water phase better matches that of the silicone oil in order to improve droplet edges visualization. This emulsion ( $\approx 10 \mu\text{L}$ ) is then injected in the chamber which is subsequently sealed with hot wax (Dental Sticky Wax from Kerr). We then acquire 2D fluorescence images of the droplet packings through spinning-disk confocal microscopy (Spinning Disc Xlight V2, Gataca systems), using a  $\times 20$  objective.

## 2.3 Image Analysis

### 2.3.1 Image Segmentation and Shape Measurements

Raw images are segmented using Ilastik [58], as illustrated in **Supplementary Figure S2B**. Segmented images are then skeletonized to obtain a binary image of the contour of droplets and a surface Voronoi tessellation is performed on the segmented images with Fiji (see **Figure 2A** and **Supplementary Figure S2C**). All subsequent image analysis are performed with the Sci-kit image Python module. At this stage, the size and circularity  $4\pi a/p^2$  are calculated for all binarized objects, with  $p$  the perimeter and  $a$  the projected surface of the identified objects. We detect two kinds of objects: voids (typical area  $25 \mu\text{m}^2$ , typical circularity 0.45) and droplets (typical area  $700 \mu\text{m}^2$ , typical circularity 0.9). Only the objects with an area larger than  $253 \mu\text{m}^2$ , (i.e., a radius  $r > 9 \mu\text{m}$ , the size of our smallest droplets) and a circularity larger than 0.67 are classified as droplets. Droplets whose Voronoi cell touch the border of the image are also excluded from the analysis.

We next calculate the shape parameter  $\mathcal{A} = \frac{p^2}{4\pi a}$  for each droplet in the packing. In order to smooth out the roughness due to pixelation of the images, the perimeter of the droplets is computed using the method described in [55]. Briefly, a Savitzky-Golay filter is applied to the contour to smooth it out, then the contour is locally approximated with osculating circles, as

illustrated in **Supplementary Figure S2G, S3**. This contour is then used to compute the perimeter and area of the droplet. Finally, the local packing fraction  $\rho_l$  is computed for each droplet as the ratio between the droplet area  $a$  and the corresponding Voronoi cell area.

### 2.3.2 Neighborhood and Adhesion Patches Measurements

The Region Adjacency Graph [59] module from the Sci-kit image Python package [60] was used to determine the neighborhood properties in the packing, as illustrated in **Supplementary Figure S2D**. In particular, for a given droplet, the number of neighbors  $n$  refers to adjacent Voronoi cells. Within those neighbors, a number of droplets are in direct contact with the central one, thus defining its number of contacts  $z$ , i.e., its coordination number (see **Supplementary Material** for more details).

For every droplet-droplet contact, we detect the presence of an adhesion patch by comparing the fluorescence intensity in the contact to the one on the free surface of the droplet. For two droplets of the same color, we identify a binding patch if the fluorescence intensity at the droplet-droplet contact is at least twice larger than the intensity on the free surface (for more details, see **Supplementary Material** and **Supplementary Figure S4**). Moreover, we only consider patches that are larger than  $1 \mu\text{m}^2$  in order to exclude artifacts such as small protein aggregates (see **Supplementary Figure S2F** for an example of detected patches and aggregates). For DNA complementary droplets of different colors, the fluorescence intensity in the patch is not additive. We identify a binding patch when the intensity in the patch is 1.5 times larger than the intensity on the free surface for each color. This threshold was chosen using the intensity histogram of the image, and adjusted by trial and error to match the patches detected by eye, as is explained in more details in section 2.4 of the **Supplementary Material**.

The local adhesiveness of a droplet  $Q_l$  is defined as the ratio between its number of contacts displaying an adhesive patch  $z_a$  and its total number of contacts with the surrounding droplets  $z$  (see two examples in **Figure 2A**).

### 2.3.3 Void Measurements

Regions discarded from the droplet analysis are the void areas between droplets. We excluded all the voids touching the border of the images from the analysis. For each void, we counted the number of corners detected with a Harris corner detector [61], and assumed that the number of corners was equal to the number of sides of the voids, as shown in **Figure 2B**. Then for each image, we measured the packing fraction (as the total area fraction of the droplets on the image), and the probability of a void having  $n$  sides on the image.

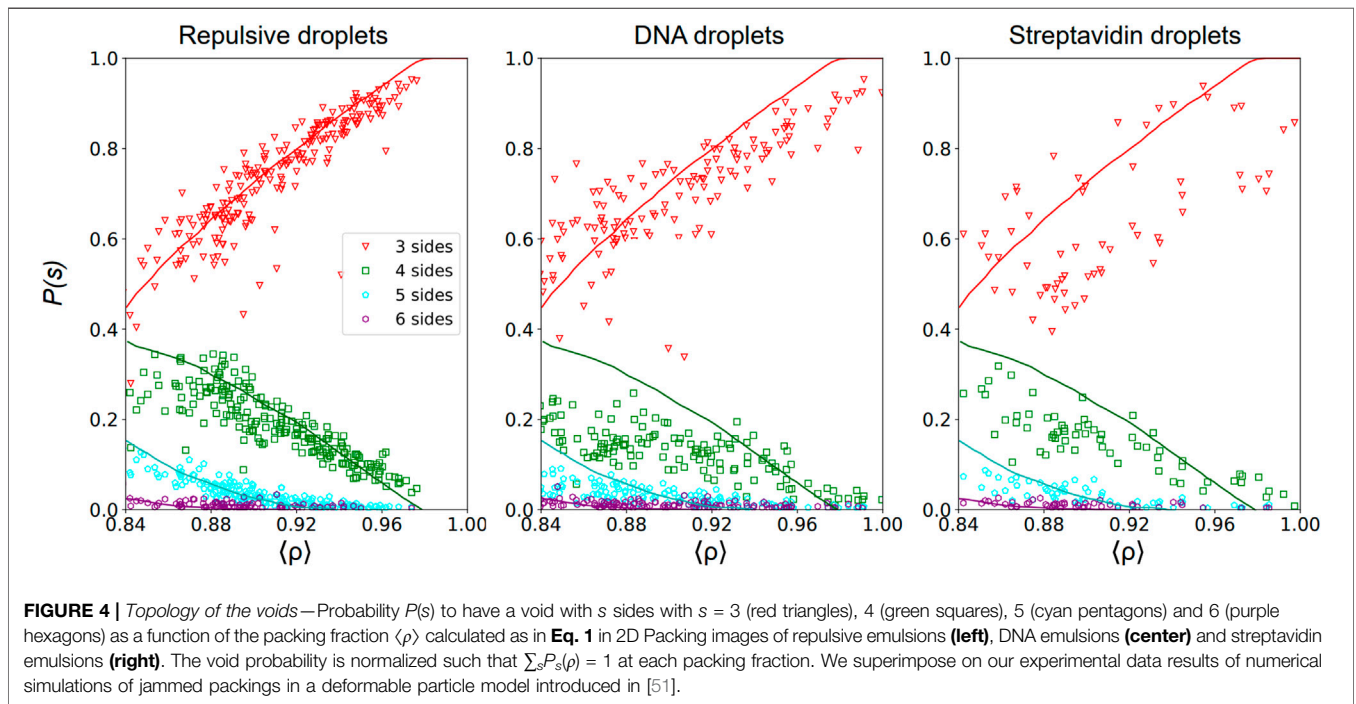

## 2.4 Experimental Conditions

Two-dimensional packings of droplets were prepared as described in the Materials and Methods section. Six distinct experimental conditions were explored in order to tune the number of adhesive droplet-droplet contacts in the packings. To do so, we used droplets coated with streptavidin or DNA complementary strands and, in the latter case, explored a range of

ratios for the droplets carrying each strand of DNA. For each condition, we calculated the resulting global adhesiveness  $Q_g$  by averaging the local adhesiveness of all droplets in all images corresponding to a given experimental setting (for instance one given ratio of complementary DNA droplets).

Packings of non-adhesive droplets were prepared by using streptavidin coated droplets in the absence of the salts necessary to trigger adhesion (in the so-called TS buffer). In the absence of salt, it was shown that compression could lead to biotin-streptavidin-biotin patches between droplet surfaces over the timescale of hours [52, 55]. To avoid this effect in the case of control experiments, we imaged the samples immediately after they were formed, which indeed yielded a close to zero adhesiveness ( $Q_g = 2\%$ ). To complement these control experiments, we also prepared packings of DNA coated droplets in which only one strand was introduced, namely the C strand. In the absence of a complementary strand to hybridize with, these emulsions also displayed a zero adhesiveness (see **Figure 2C**). As a result, these experiments were pooled together and labelled as *repulsive* packings [52, 55]. Adhesive emulsions were prepared with two distinct strategies. First, we used streptavidin biotin adhesion between the droplets in order to maximize the number of potentially adhesive contacts between the droplets. Second, we used droplets coated with complementary strands of DNA such that only a fraction of the contacts on average can form an adhesion [57]. For streptavidin driven adhesion, the droplets were incubated for 90 min in TM2S buffer in the observation chamber, allowing adhesive patches to form between contacting droplets. We refer to these conditions as *Streptavidin droplets* experiments in the following. The adhesiveness of these emulsions was measured to be  $Q_g = 57\%$ , as shown on **Figure 2C**. Note that the adhesiveness does not reach 100%, meaning that not all contacts are adhesive. This is due to the fact that the number of available streptavidins or biotins to form patches can differ from one droplet to the other, and may not allow to form patches with all contacting droplets. Moreover, as binders may cluster inside the adhesive patches, a droplet can run out of binders to form additional patches with the other contacting droplets, which could account for the limited adhesiveness in these packings.

In addition to this, partially adhesive droplets experiments were prepared by using various proportions of droplets functionalized with complementary DNA strands. Two distinct sets of complementary strands were used: C/D or C/D' (see Materials and Methods). Since both pairs of DNA strands display the same number of complementary bases, they have the same binding energy of about  $26 k_B T$  [62]. The experiments carried out with C/D or C/D' strands were thus pooled together. The complementary droplets were mixed together immediately before injection in the chamber in proportions ranging from 1:9 (for instance  $1.5 \mu\text{L}$  of C emulsion mixed with  $13.5 \mu\text{L}$  of D emulsion), to 1:3, 1:2 and 1:1. The 1:1 DNA experiment had a mean adhesiveness of 46% as seen on **Figure 2C**, and is labelled *DNA droplets* in **Figures 3, 4**. The resulting global adhesiveness  $Q_g$  in the packings for the different

proportions of complementary droplets is shown in Figure 2C. The  $Q_i$  cumulative distribution for each global adhesiveness  $Q_g$  is available on Supplementary Figure S5.

After sample preparation and injection in the microfluidic chamber, fluorescent images were acquired at various locations in the sample. Each captured region of interest contains  $\sim 200$ – $300$  droplets. After image analysis, we obtain for each droplet  $i$  its area  $a_i$  and the area of its associated Voronoi cell  $A_i^v$ ; this provides us information about its local packing fraction  $\rho_i = a_i/A_i^v$ . We also extract for each droplet its number of contacts (or coordination)  $z_i$  (see Materials and Methods) and neighbors  $n_i$ .

### 3 RESULTS

#### 3.1 Structural Properties of Static Packings

Isotropically compressed systems composed of repulsive and frictionless particles, such as emulsions, typically jam and develop a non-zero yield stress at a critical packing fraction  $\rho_c \approx 0.84$  [24, 63, 64]. For  $\rho < \rho_c$ , the particles have an insufficient number of interparticle contacts for the packing to be mechanically stable. At the jamming onset, Maxwell’s criterion dictates that the average coordination in 2D disordered packings of repulsive spheres be given by  $z_c = 4$ ; in other words, the packing develops a connected interparticle contact network which is

exactly isostatic at the critical point  $\rho_c$  [24, 63, 65, 66]. If the system is further compressed to  $\rho > \rho_c$ , the average coordination is expected to increase. We first study how the coordination number grows with the packing for adhesive and non-adhesive packings. To do so, we look at each image independently and measure their average coordination and packing fraction, given respectively by  $\langle z \rangle = N^{-1} \sum_{i=1}^N z_i$  and

$$\langle \rho \rangle = \frac{\sum_{i=1}^N A_i}{\sum_{i=1}^N A_i^v} \quad (1)$$

where the sum runs over the number of droplets which sit entirely in the frame. We compare the data obtained for non-adhesive packings with the two most adhesive conditions: streptavidin packings (corresponding to  $Q_g = 0.57$ ) and DNA packings with a 1:1 ratio (corresponding to  $Q_g = 0.46$ ). As seen in **Supplementary Figure S7**, the average coordination increases with the global packing fraction and our data is in agreement with recently developed models of deformable particles (in which droplets are deformable but cannot overlap, see **Supplementary Material**). Note that in this representation, adhesive and repulsive conditions overlap above the jamming onset, which does not allow us to test the effect of adhesion for the packing of deformable particles.

### 3.2 Local structural Properties of Static Packings

We then study the local structural properties of static packings. In particular, we look at the local neighborhood properties of particles in the framework of the granocentric model [67–69]. According to this model, random packings of frictionless spheres can be described locally by the assembly of nearest neighbors around a central particle. After filling the available solid angle around it, one randomly chooses which of those neighbors are in contact with the central particle. The granocentric point of view thus reduces the complexity of understanding the global structure of packings to a local stochastic process.

We first examine the relationship between the area of the Voronoi cell associated to each droplet and its number of neighbors  $n$  (i.e., the number of faces of the Voronoi cell). Qualitatively, one expects that larger droplets can accommodate a higher number of neighbors around them. In our experiments, we find that the average area  $\langle A_n \rangle$  of cells with  $n$  neighbors normalized by the average area over all cells  $\langle A \rangle$  increases nonlinearly with the number of neighbors  $n$  (see **Figure 3A**) as was previously observed for soap foams and emulsions in 3D (in which one instead considers the volume of the Voronoi cells) [71]. Strikingly, we find that all adhesion conditions follow the same law and are in agreement with previous extensions of the granocentric model in 2D [70]. This independence with respect to adhesion hints at the fact that repulsive and adhesive emulsions pave space the same way, i.e., their Voronoi cells have the same number of neighbors for a given size. Rather, the difference between repulsive and adhesive emulsions is to be found in the statistics of their number of contacts which is the local parameter that should be sensitive to interdroplet adhesion.

To study this in further detail, we measure the coordination of each droplet  $z$  (i.e., its number of contacts) as a function of its local packing fraction  $\rho$ . We find that adhesive droplets maintain a higher coordination than repulsive droplets at low packing fractions ( $\rho < \rho_c$ ), see **Figure 3B**. In fact, DNA emulsions exhibit local coordination numbers that are located above the value of 3, corresponding to the minimum  $z$  for local mechanical stability, far below jamming. This is in agreement with previous observations on packings of attractive droplets in which voids were stabilized with attraction, leading to mechanically stable structures below the jamming transition [40]. At high local packing fraction  $\rho \sim 1$ , the coordination of repulsive droplets converges to  $z = 6$ . Indeed, compression is accompanied by structural rearrangements in these packings of non-adhesive droplets. While polydisperse emulsions are fully disordered close to jamming, local crystalline order is expected to emerge under compression. This will lead to locally hexagonal lattices associated to a coordination  $z = 6$  in 2D. In contrast, we can observe a slight deficit in coordination in strongly adhesive emulsions when  $\rho$  approaches 1 (see inset for DNA functionalized droplets in **Figure 3B**). Qualitatively, this observation is in agreement with the fact that adhesion impairs one degree of freedom in the system. This might also explain why the effect is only visible for DNA bonds that have a higher binding energy of  $\approx 26k_B T$  [62] than streptavidin-biotin bonds associated with  $\approx 15k_B T$  [72, 73]. Indeed, while adhesion patches between droplets can move freely on their surface [57], their rupture is energetically costly which hinders the reorganizations that are leading to local ordering of the system.

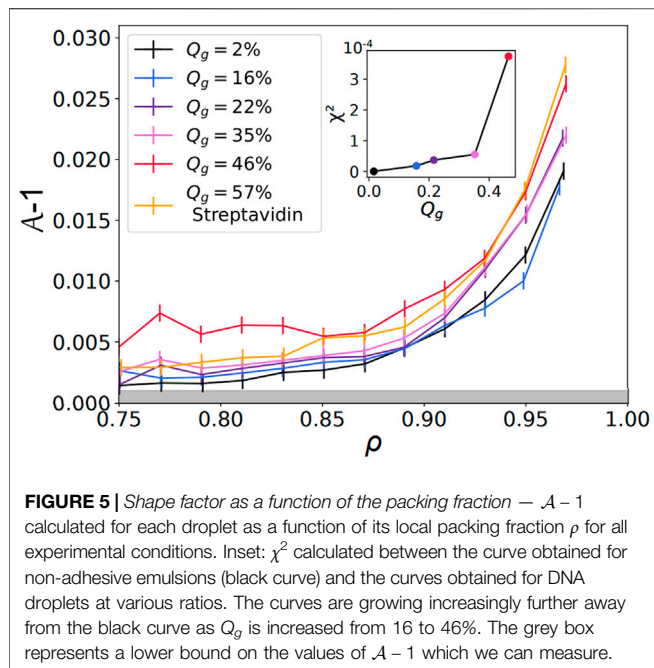

To further quantify the emergence of local order in our emulsions, we measure the positional order in our packings as a function of adhesion. To do so, we calculate the bond orientational order parameter  $\psi_6$  which measures hexagonal crystalline order [74, 75]. The local bond orientational order is given by

$$\psi_6^l = \frac{1}{n_k} \left| \sum_{j=1}^{n_k} e^{6i\theta_{kj}} \right| \quad (2)$$

where  $n_k$  is the number of neighbors of drop  $k$ . The angles  $\theta_{kj}$  are defined as the angle between the vector joining the centers of droplet  $k$  and one of its Voronoi neighbors  $j$  and an axis of reference. Here, we focus on the local definition of the bond orientational order as polydispersity would prevent any long-range crystalline order. Indeed, in a polycrystalline system, one potentially observes large values of  $\psi_6^l$  even though the global bond orientational order can be very low.

In **Figure 3C**, we represent the average  $\psi_6^l$  as a function of the local packing fraction. We observe a characteristic increase of the local bond orientational order corresponding to the fact that compression above the jamming threshold promotes local crystalline order through structural rearrangements. Furthermore, the difference between the  $\psi_6^l$  calculated for repulsive and adhesive conditions above jamming is always negative and decreasing with increasing  $\rho$ , as illustrated in the inset in **Figure 3C**. In other words, adhesion hinders local crystalline order even at high packing fraction. As adhesion

**FIGURE 5** | Shape factor as a function of the packing fraction  $\mathcal{A} - 1$  calculated for each droplet as a function of its local packing fraction  $\rho$  for all experimental conditions. Inset:  $\chi^2$  calculated between the curve obtained for non-adhesive emulsions (black curve) and the curves obtained for DNA droplets at various ratios. The curves are growing increasingly further away from the black curve as  $Q_g$  is increased from 16 to 46%. The grey box represents a lower bound on the values of  $\mathcal{A} - 1$  which we can measure.

patches move freely on the surface of the droplets, strong adhesion patches only allow structural rearrangements which do not necessitate interdroplet contact breaking. As stresses in the adhesive packings can not be released as efficiently by structural rearrangements, we expect droplet deformation to be significantly higher in adhesive emulsions.

### 3.3 Void Statistics

To characterize fully the local topology of the packings, we further study the structure of the voids between droplets as a function of the mean packing fraction  $\langle \rho \rangle$  above jamming in each image. From our image segmentation, we can extract the void space and characterize the topology of the voids by counting their number of edges.

In **Figure 4**, we represent the probability  $P(s)$  to have a void with  $s$  sides in repulsive, DNA and streptavidin emulsions as a function of the global packing fraction calculated in each acquired image. For repulsive packings, we observe that the probabilities of three- and 4-sided voids are similar near the jamming onset  $\rho_c$  and greatly exceed the probability of having 5- or 6-sided voids. As the packing fraction increases, structural rearrangements lead to a strong increase of the probability of 3-sided voids while the probability of finding any other type of voids decreases, which is consistent with the emergence of hexagonal order at higher packing fractions. In **Figure 4**, we show quantitative agreement between our experimental data for repulsive emulsions and results of numerical simulations of jammed packings in a deformable particle model [51]. Instead, analysis results for adhesive packings (both DNA and streptavidin droplets) deviate from the numerical results of this purely repulsive model. All distributions are flatter in both cases and the proportion of 3-sided voids are consistently lower than the theoretical curve derived for repulsive packings at high packing

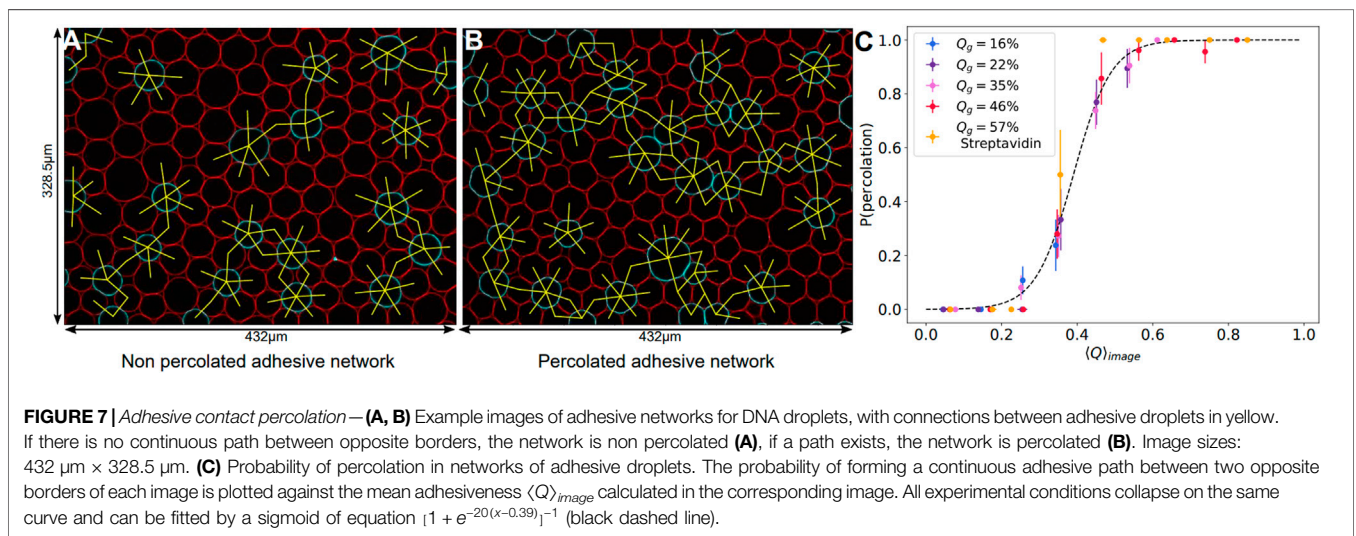

fractions. This is again consistent with the idea that adhesion prevents local ordering upon compression in such emulsion packings, or in other terms that droplets have less freedom to rearrange. This would lead in turn to more constrained void topologies as evidenced by distributions that are less sensitive to the packing fraction.

### 3.4 Local Deformations and Adhesion

We next study the deformation of the droplets as a function of their local packing fraction. To do so, we measure the shape parameter  $\mathcal{A} = \frac{p^2}{4\pi a}$  of each droplet in the packings (see Materials and Methods). The presence of adhesion patches should induce additional deformations, i.e., higher values of  $\mathcal{A}$ , by locally flattening the contact area between contacting droplets. As shown in **Figure 5**, when plotting  $\mathcal{A} - 1$  against the local packing fraction, we observe that the curve corresponding to repulsive emulsions (black curve) is located below the highest 2 DNA conditions and streptavidin curves. Moreover, for DNA experiments, an increase in global adhesiveness induces an increase in deformation for a given packing fraction. This trend is evidenced by calculating the least-squares measure  $\chi^2$  between the repulsive emulsion curve and all DNA experiment curves as a function of their calculated global adhesiveness (see inset in **Figure 5** and **Supplementary Material**). This simple way of quantifying the spacing between experimental curves highlights the increase of deformation with increasing average adhesiveness.

Finally, the curve corresponding to streptavidin experiments, at  $Q_g = 57\%$ , is located below the highest DNA curve at  $Q_g = 46\%$ . This shift can be explained by the difference in binding energy between these two types of binders. Indeed, a biotin-streptavidin bond is associated with an energy gain of about  $\approx 15k_B T$ , while a sticky DNA sequence of 11 base pairs is estimated to yield  $\approx 26k_B T$ . As the size of an adhesion patch between two droplets is set by the balance between the binding energy gain upon adhesion versus the elastic cost due to surface deformation, higher binding energies per bond could lead to larger patches and higher values of  $\mathcal{A}$ , explaining why DNA emulsions are significantly more deformed than streptavidin ones at comparable global adhesiveness.

Surprisingly, the trend is very different if one looks at *local* droplet adhesiveness  $Q_l$  within one experimental condition, i.e., one given  $Q_g$ . Indeed, we sorted all the droplets in one given condition as a function of their local adhesiveness and pooled them in bins of local adhesiveness  $Q_l$ . For each bin, one can plot again the evolution of their shape factor as a function of the local packing fraction. Strikingly, one can see with this representation that the curves overlap independently of their  $Q_l$ , as evidenced both for DNA and streptavidin emulsions in **Figures 6A–C**. This observation is again quantified by a calculation of the  $\chi^2$  value between the control curve and all other ones at higher local adhesiveness (see **Supplementary Figure S6**). We conclude from this analysis that the droplets cannot be separated from each other as a function of their local adhesiveness  $Q_l$  within a given experimental condition (associated to a given  $Q_g$ ). In other words, this means that the non-adhesive droplets within adhesive packings display the same

behavior as the whole packing independently of their local binding topology. Qualitatively, if a non-adhesive droplet is caged by a ring of adhesive ones, one can understand how the contraction of this adhesive ring will automatically induce deformations in the central droplet, as illustrated in **Figure 6D**.

Therefore, a continuous cage of adhesive droplets should be sufficient to induce deformation on all the non-adhesive droplets enclosed in that chain. Conversely, if adhesive contacts are too sparse, individual non-adhesive droplets will not *feel* the adhesion. In order to quantify this effect, we measured the percolation of adhesive contacts within all emulsions. We defined the adhesive network as the network formed by contacts displaying an adhesive patch. For each image, we check the existence of a path along the adhesive network going from any droplets on one border to any droplet on the opposite border of the image, as shown in **Figures 7A,B**. If at least one such path exists between two opposite borders, the network on the image is classified as percolated. We then measure the average adhesiveness in each of these images and plot the probability of percolation as a function of the image adhesiveness for all experimental conditions. We find that, independently of the  $Q_g$  value, all points superimpose onto a master curve showing a sharp transition between packings with non percolating and percolating conditions (see **Figure 7C**). We thus argue that the mechanical properties and local structure of our packings are controlled by a percolation transition for adhesive contacts. We fit the experimental points by a sigmoid function and obtain a critical value of 0.39 for the global adhesiveness above which packings are percolated, which coincides with the value at which the deformation curve significantly deviated from the repulsive case (see inset of **Figure 5**).

## 4 DISCUSSION

In recent years, approaches borrowed from soft matter have led to the introduction of new frameworks to decipher the physical ingredients at the origin of important biological processes. For instance, recent studies have highlighted the importance of a precise regulation of the mechanical properties of tissues for the shaping of organs during morphogenesis [2, 5–9]. In this context, cell-cell adhesion has been identified as a key parameter in the control of the viscoelastic behavior of tissues. Cellular adhesion is expected to impact the mechanical properties of tissues at multiple levels; indeed, it can tune the topology of cellular tilings [36, 38–40], but also modify their elasto-plastic response under perturbation [54, 55].

Here, we have developed a simplified approach to probe the role of adhesion on the local structure and rigidity of cellular monolayers based on the study of static 2D packings of biomimetic emulsions. In particular, we mimic cellular tissues by using functionalized droplets with controllable adhesion properties. The use of different types of binders between the functionalized droplets allows us to control not only the binding energy between the droplets, but also to tune the structure of the network of adhesive contacts in the 2D packings, by

varying the proportion of droplets carrying complementary binders in the emulsion.

The strength of the interdroplet adhesion depends on both the binding energy and the density of binders in the adhesion patches. We calculate the density of binders in the adhesive patches by using a force balance model [76]. To do so, we focused on configurations below the jamming transitions to approximate each droplet as a portion of a sphere and a flat region corresponding to the contact area (**Supplementary Figure S8**). Imposing the force balance equation in the system, i.e., considering the droplets at a stationary state in mechanical equilibrium, we obtained an expression for the average binder density  $\rho_{link} = \frac{2\gamma}{E_b} \left[ 1 - \sqrt{1 - \left(\frac{R_c}{R}\right)^2} \right]$ , where  $\gamma$  is the surface tension at the oil-water interface,  $E_b$  is the binding energy per bond,  $R_c$  is the radius of the adhesive patch and  $R$  is the radius of the droplets (see details in **Supplementary Material**). We find the values of  $R_c$  through the image analysis of the bonds between uncompressed droplets below jamming. By using  $E_b = 15k_B T$  and  $R_c = (3.9 \pm 0.15) \mu\text{m}$  for streptavidin-biotin bonds, and  $E_b = 26k_B T$  and  $R_c = (4 \pm 0.05) \mu\text{m}$  for DNA bonds,  $\gamma = 10 \text{ mN/m}$ , and  $R = 15 \mu\text{m}$ , we obtained  $\rho_{link} = (10,874 \pm 859) \mu\text{m}^{-2}$  for streptavidin-biotin patches and  $\rho_{link} = (6,728 \pm 171) \mu\text{m}^{-2}$  for DNA patches as estimates for the binder densities in the two different conditions. These numbers are in remarkable agreement with values reported for the adhesion zones between cells in epithelial tissues [77], which further validates the relevance of our biomimetic approach. Moreover, the difference between the densities of streptavidin-biotin and DNA bonds may arise from entropic effects. Indeed, this model does not take into account the entropic cost of binders hybridization between opposing surfaces inside a patch. Since this energetic cost depends directly on the rotational constraints of the molecules upon binding [57, 78], it should be different for the two types of binders that have different geometries. This highlights the importance of not only the binding energy but also the structural properties of the molecules that are responsible for cell-cell or cell-matrix adhesion in tissues. For instance, cadherins can exhibit large differences in their binding topology depending on biochemical processes [79], which should have significant effects on the mechanics of the tissue as a whole.

Besides differences in the intercellular interaction potential, in such particulate systems the mechanical response directly depends on its structure in the framework of the jamming transition. We therefore studied the impact of adhesion on the structural properties of static packings. Below jamming, we observed that adhesive droplets form more locally stable structures by having a higher number of contacting neighbors than in the repulsive case, remaining above isostaticity far below the jamming volume fraction for repulsive systems. This is consistent with existing literature showing that adhesive emulsions can exhibit a finite elastic modulus below jamming [43, 48]. Conversely, packings with strong interdroplet adhesion reveal a deficit in droplet coordination number and lower bond orientational order parameter when approaching confluence. We argue that this is due to the fact that adhesion prevents local crystalline order by preventing droplet rearrangements which would require breaking adhesive bonds. By preventing ordering,

adhesion can have an impact on the response of compressed emulsions under stress as higher crystalline order in particulate materials has been shown to promote large rearrangements along disclination planes when subjected to shear [55, 80, 81].

Rearrangements in jammed packings participate in the release of stored elastic energy; as adhesion prevents these rearrangements, it is then not surprising that adhesion would promote higher droplet deformation in compressed emulsions. We confirm this intuition and show more specifically that the deformation level in adhesive emulsions is controlled by a percolation transition. Indeed, we observed that percolation of the network formed by adhesive contacts in the packing sets the level of deformation for all droplets, independently of their local environment. More precisely, we found that 40% of adhesive contacts are sufficient to induce a global change in the deformation level of all droplets in the assembly. Qualitatively, percolated networks of adhesive interdroplet contacts promotes local caging of droplets surrounded by strong adhesion rings. Droplets in these cages will thus display the same level of deformation as surrounding droplets with high adhesiveness independently of their own adhesiveness.

Going back to biological tissues, our observation means that the upregulation of adhesion in a small number of cells could induce large global changes in the tissue through mechanosensitive pathways. We argue that the tissue rigidity transition, which is key to fundamental morphogenetic processes, can thus take place with only a low fraction of adhesive contacts between the cells given that their spatial distribution ensures percolation of the adhesive contacts network. Interestingly, a recent study argues that a rigidity percolation transition similar to ours controls the mechanical properties of the zebrafish blastoderm throughout morphogenesis but also across experimental perturbations of cell fate, division, contractility and adhesion [23]. Akin to our observation, it was shown that cell-cell adhesion defines the cell connectivity which in turn, modulates the tissue rigidity. In particular, small changes in cell-cell adhesion were linked to drastic and abrupt changes in tissue viscosity. Overall, this is all consistent with the idea that being close to the rigidity percolation critical point allows a tissue to change its material properties rapidly and drastically [82].

In conclusion, our work explores the physics of jamming and rigidity percolation in tissues from two perspectives. First, from a granular point of view, the structural properties of the packings are controlled by the packing fraction. In this context, we confirm here that adhesion stabilize packings at densities below the jamming onset for repulsive systems. In that sense, the jamming onset (understood as the critical

density at which the packing acquires a non zero yield stress) should be defined at a lower threshold packing fraction in the presence of adhesion. Importantly, we further show that long range collective effects control the deformation of individual droplets in our system. We argue here that this observation can be understood in the context of the transition to percolation of the adhesive contacts network. Our work thus paves the way for a redefinition of the jamming phase diagram for tissues, in which the axis related to the intercellular adhesion energy (or the packing fraction) could be replaced by a measurement that combines this value with the spatial arrangement of the adhesive interfaces.

## DATA AVAILABILITY STATEMENT

The raw data supporting the conclusions of this article will be made available by the authors, without undue reservation.

## AUTHOR CONTRIBUTIONS

L-LP conceived the project, LM and IG performed experiments, TB and SG performed theoretical modelling, LM and TB performed data analysis. L-LP, TB, and LM wrote the original draft, SG, EW, and AP reviewed and edited the manuscript. All authors participated to scientific discussions on the results and commented on the manuscript.

## FUNDING

L-LP acknowledges financial support from Agence Nationale de la Recherche (BOAT, ANR-17-CE30-0001) and from Emergence(s) Ville de Paris.

## ACKNOWLEDGMENTS

The authors thank Corey S. O'Hern for sharing the numerical data shown in **Figure 4**, as well as Jacques Fattaccioli for letting us use his pressure emulsifier.
