Abstract

Objectives: The ASSIST study investigated prescribing in routine psoriatic arthritis (PsA) care and whether the patient reported outcome: PsA Impact of Disease questionnaire (PsAID-12), impacted treatment. This study also assessed a range of patient and clinician factors and their relationship to PsAID-12 scoring and treatment modification.

Methods: Patients with PsA were selected across the UK and Europe between July 2021-March 2022. Patients completed the PsAID questionnaire, with the results shared with their physician. Patient characteristics, disease activity, current treatment methods, treatment strategies, medication changes and patient satisfaction scores were recorded.

Results: 503 patients recruited. 36.2% had changes made to treatment, 88.8% of this had treatment escalation. Overall, the mean PsAID-12 score was higher for patients with treatment escalation; the PsAID-12 score was associated with odds of treatment escalation (OR: 1.58; $p < 0.0001$). However, most clinicians reported PsAID-12 did not impact their decision to escalate treatment, instead supporting treatment reduction decisions. Physician's assessment of disease activity had the most statistically significant effect on likelihood of treatment escalation, (OR = 2.68, per 1-point score increase). Escalation was more likely in patients not treated with biologic therapies. Additional factors associated with treatment escalation included: patient characteristics, physician characteristics, disease activity and disease impact.

Conclusion: This study highlights multiple factors impacting treatment decision making for individuals with PsA. PsAID-12 scoring correlates with multiple measures of disease severity and odds of treatment escalation. However, most clinicians reported the PsAID-12 did not influence treatment escalation decisions. PsAID scoring could be used to increase confidence in treatment de-escalation.

Keywords: Psoriatic arthritis, PsA, Quality of life, PSAID, PSAID-12, ASSIST, HAQ, EQ-5D-5L, Patient reported outcomes

Key messages:

- This study highlights multiple factors on decision making when reviewing treatments for individuals with PsA.
- The heterogeneity of clinical phenotype, with increasing number of effective therapies necessitates collaborative treatment decision-making.

Introduction

Psoriatic arthritis (PsA) is a chronic musculoskeletal inflammatory disease. [1] As a result of the diversity of clinical presentation and treatment responsiveness there is often need for personalization of the therapeutic approach. Currently little is known about the factors underpinning treatment choices in routine practice. [2,3]

Patient reported outcome measures (PROMs) have been developed to measure disease activity, both guiding treatment decisions in clinical standard and standardizing outcomes in clinical research. [4] The PsA Impact of Disease questionnaire (PsAID) is a disease-specific patient reported outcome (PRO) co-designed by clinicians and patients to measure the overall impact of psoriatic disease from the patient perspective and also put forward in OMERACT and GRAPPA meetings. [5,6,7] There are two versions of the PRO: a 9-item questionnaires for use in clinical trials and a longer 12-item questionnaire with simplified scoring for clinical practice.[2] The PsAID-12 was designed for use in clinical practice to monitor patients and identify areas that might require intervention in ongoing clinical management. It has been validated in a number of observational studies and interventional trials. [5,9,10,11,12] The MERECES study proposed PsAID as a standard tool for evaluating the impact of disease and also as an essential instrument in making therapeutic decisions in PsA. [8] However, there is limited data on its use in routine practice.

The purpose of the ASSIST study was to investigate the prescribing practice for PsA in routine care and whether the use of the patient reported outcome (PRO), PsA Impact of Disease questionnaire (PsAID-12), impacted treatment decisions in the post-COVID era.

To understand more about the consultations of patients with PsA and factors that underpin decisions to change treatment, we also recorded measures of satisfaction in consultation and measure of shared decision making in practice. By comparing treatment data between countries, we can understand more about factors influencing treatments patients receive, patient outcomes and establish international benchmarks in practice.

Methods:

The ASSIST study was a cross-sectional analysis of adult patients aged 18 years and older, attending a face-to-face rheumatology appointment, with a clinical diagnosis of PsA made previously by a rheumatologist (meeting the Classification of Psoriatic Arthritis criteria). [13] Patients were selected by systematic sampling from 24 centres across 5 countries (UK, France, Germany, Italy, and Spain) between July 2021 and March 2022. Ethical approval was specifically gained for this research study via London - Camden & Kings Cross Research Ethics Committee research: Ethics reference: 20/PR/0587 and has been listed via the IRAS platform: IRAS ID: 287039. This project was funded by an unrestricted project grant from Amgen.

Patients:

Patients were aged 18 years and older attending a face-to-face appointment, with a known diagnosis of PsA made by a rheumatologist. Patients were excluded from the study if they had a new diagnosis of PsA at the current clinic visit; were not comfortable completing an app-based questionnaire or paper case-report form; or unable to speak/read the local language. Given our aim to analyse factors

1
2
3 underpinning treatment decisions, a target sample size of 100 patients per country was chosen
4 based on data that 32% of patients undergo a treatment change at a clinic appointment. [14]
5

6 Each centre aimed to recruit the same number of patients. Patients were selected using systematic
7 sampling with random starting numbers generated for each site. Participants gave written informed
8 consent.
9

10 The primary objective was to assess the influence of the PsAID-12 score on likelihood of treatment
11 escalation. Therefore, the PsAID questionnaire was completed by the patient prior to the
12 appointment and the scores shared with the treating physician in their standard appointment.
13 Patients were treated in their routine clinical practice. Patient and disease characteristics, current
14 treatment methods and decisions on treatment strategies (medications unchanged, switched, added
15 or reduced) were recorded.
16
17

18 This study was developed to look at different aspects of the disease and the associations between
19 these and treatment change. Patient and disease characteristics were recorded, including: patient
20 demographics, PsA duration, prior and current treatment, number of comorbidities (according to the
21 functional comorbidity index [7]) and disease activity. Composite scores have previously been shown
22 to be associated with treatment change [8] however were not used in this study to enable clarity in
23 looking at separate (and different) aspects of the disease in greater detail and the association of
24 these with treatment change.
25
26
27
28

29 *Disease activity measures included:*

- 30
31 i) A clinical assessment including clinical history which included duration of disease and
32 prior and current treatment.
33 ii) Tender and swollen joint count. (The inclusion of axial spine disease within this
34 pragmatic study was at the discretion of the acting clinician and their assessment of
35 active disease within their routine clinical practice. No direct data was recorded on this)
36
37 iii) Dactylitis count
38 iv) Body surface area of psoriasis
39 v) Physician-rated overall assessment of disease activity score.
40 vi) Widespread Pain Index (WPI) and Severity Scale (SS) for Fibromyalgia
41 vii) Leeds Enthesitis Index (LEI). [15, 16]
42
43
44
45

46 *Participants completed PROs prior to their clinic appointment, including:*

- 47
48 i) the PsAID-12 questionnaire via the Group for Research and Assessment of Psoriasis and
49 Psoriatic Arthritis (GRAPPA) app on a tablet (scored from 0-10, with 10 reflecting worst
50 possible health)
51 ii) the numerical rating scale (NRS) for disease activity and pain
52 iii) the health assessment questionnaire (HAQ) and iv) the EQ-5D-5L. [6, 18] PsAID-12
53 scores were shared with the treating physician during the appointment. Current
54 treatment methods and treatment decisions (treatment unchanged, escalated or
55 reduced) were recorded. Escalation was defined as one or more of the following:
56 increase in current medication dose; increase in medication frequency; change in route
57 of administration; addition of a new medication; or switch to a new medication.
58
59
60

1
2
3 Comorbidities were summarized for each patient using the functional comorbidity index (FCI). [17] A
4 total score was obtained by counting the number of conditions present (range of 0 – 18). If at least
5 one condition was not classified as present or absent, then the total score was set to missing.
6 Conditions included in the scoring criteria included: Arthritis (rheumatoid and osteoarthritis);
7 Osteoporosis; asthma; chronic obstructive pulmonary disease (including acquired respiratory
8 distress syndrome and emphysema); angina; congestive heart failure (or heart disease); heart attack
9 (myocardial infarction); neurological disease (Parkinson's or multiple sclerosis); Stroke or transient
10 ischemic attack; peripheral vascular disease; Diabetes (type I or type II); upper gastrointestinal
11 disease (Ulcer, hernia, reflux); Depression; Anxiety or panic disorders; visual impairment (cataracts
12 or glaucoma); Hearing impairment; degenerative disc disease (back disease, spinal stenosis, or
13 severe chronic back pain) Obesity or body mass index over 30 kg/m² . (The number of comorbidities
14 was generally low, median of 1, with no patient having more than 11).

15
16
17
18 Participants completed PROs including the PsAID-12 questionnaire (administered using the Group
19 for Research and Assessment of Psoriasis and Psoriatic Arthritis (GRAPPA) app on a tablet),
20 numerical rating scale (NRS) for disease activity and pain, the health assessment questionnaire
21 (HAQ) and EQ-5D-5L. [20]

22
23
24 After visits, patients independently completed the following questionnaires:

- 25
26 I) The CollaboRATE questionnaire - examines the patients perception of shared-decision
27 making (scored from 0-9). [7, 8, 19]
28
29 II) The perceived efficacy in patient physician interactions (PEPPI) tool - assesses the
30 patients' view on their confidence in the patient-doctor interaction (scored from 5-25).
31 [20] Clinicians were asked to rate six possible factors influencing their treatment choice
32 in each case: joint/entheseal activity, skin disease activity, patient-reported outcomes,
33 tolerance of current medication and adherence to current medication.
34

35 These two questionnaires were completed by the patients independently and the completed
36 questionnaires were not seen by clinic staff to avoid any influence being exerted on the patients.
37

38 At the end of the study, each participating physician was asked to provide their views on the
39 PsAID12 instrument. Brief details of the participating centres were collected, including the size of the
40 PsA population at the site, as well as demographic details of the physicians.
41

42 Our primary outcome variable was escalation of PsA treatment by the clinician. Escalation was
43 defined as one or more of the following treatment decisions being made at the study visit: increase
44 in dose of current medication; increase in frequency of dose administration; change in route of
45 administration; Initiation of a new medication; initiation of a new medication as a switch from
46 existing DMARD therapy.
47

48
49 Secondary outcome variables included: PSAID-12 score; CollaboRATE satisfaction with consultation;
50 perceived efficacy on patient-physician interaction (PEPPI). [1, 12, 22] The perceived efficacy in
51 patient-physician interactions (PEPPI) tool was used to assess the patients' view on their confidence
52 in the patient-doctor interaction.
53

54
55 This study also aimed to: evaluate the impact of reviewing the PsAID-12 score on the decision to
56 change treatment; assess the effects of other factors that influence the likelihood of treatment
57 escalation; determine which factors physicians feel influence treatment decisions in routine practice;
58 evaluate patient satisfaction and perceived patient efficacy in the consultation and examine how this
59
60

links to PsAID-12 score and change in treatment. We also looked to explore physicians' views on the use and value of the PsAID-12 tool.

Each centre aimed to recruit the same number of patients aiming at 100 patients per country. Patients were selected using systematic sampling with random starting numbers generated for each site.

Statistical analysis:

Statistical analysis was completed on SAS® Version 9.4. [21] There was no imputation of missing data. The initial sample size calculation was based on the need to estimate the percentage of patients for whom treatment was modified, with a stated degree of precision. This was defined as a 95% confidence interval for the percentage with width 10 percentage points. This is based on data from the GRACE study which recruited 503 patients worldwide and found that 32% underwent a treatment change, the majority being escalation for active disease. [23] For a percentage of 30% (i.e. 30% of patients requiring treatment change), a study of 333 patients would have 80% power to estimate a percentage of 30% requiring change with a confidence interval of $\pm 5\%$.

The overall probability of treatment being escalated predicted by the mean PsAID score, adjusted for clinic was estimated with associated 95% confidence interval. The effect of the total PSAID score on the probability of modifying treatment, adjusting for clinic, was expressed as an odds ratio for unit increases in PSAID score with associated 95% confidence interval. To assess the effect of the PSAID total score on treatment escalation, the total score was added to the basic logistic regression model as an independent continuous variable. The same sampling weights and variance estimation method were used as described above for the basic model. The effect of PSAID was then assessed by comparing the deviance for the two models.

Results:

There were 503 patients recruited from 24 centres (49.1% F, mean age: 53; Median patient age: 55 years) (Table 1). Mean disease duration was 10.8 (s.d. 9.28) years. The most common PsA subtype was peripheral arthritis in all countries (83.7%). The mean physicians' assessment of disease activity across countries was 3.0 (range 0-9), indicating that disease severity was generally mild (Table 1). The level of disability was also low, with mean scores of 0.6 on the HAQ score, a median tender joint count of 2 and median swollen joint count of 0. Overall, the mean total PsAID score was 3.6. Notably, both physician and patient reported outcomes in the UK indicated higher levels of disease activity and disease impact than other European countries (Table 1).

Current prescribing practices are shown in Table 2. Notably, a higher percentage of UK patients are managed with conventional synthetic DMARDs (csDMARDs) than mainland Europe (66.4% vs 44.9%), whereas use of biologics is more frequent in mainland Europe than the UK (68.1% vs 36.4%). Overall, treatment was changed for 182 patients (36.2%), with an increase in treatment being the most common type of change in this group (160 patients, 88.8%) (Table 3). The treatment increase consisted of medication addition (14.1%), medication switch (10.7%) or an increase in dose, frequency or change in route from oral to subcutaneous methotrexate (9.3%). Notably, treatment escalation was more common in the UK than Europe, commonly being a treatment escalation. This may reflect the higher level of physician and patient reported disease activity, the predominance of

1
2
3 csDMARD use or the younger patient demographic in the UK, as treatment escalation is more likely
4 earlier in the disease course.
5

6 When examining the relationship between PsAID-12 score and treatment escalation, we found that
7 the mean PsAID-12 score for patients with treatment escalation was higher than that for those
8 without escalation in 22/24 sites (Figure 1). The PsAID-12 score was associated with the odds of
9 treatment escalation (OR: 1.58; $p < 0.0001$), reflecting that the estimated odds of treatment
10 escalation increased by 58% with every 1-point increase in the score. A Receiver Operating
11 Characteristic (ROC) curve (Figure 2) demonstrates the value of the PsAID score as a predictor of
12 treatment escalation.
13
14

15 Overall, the mean total PsAID score was 3.6. The mean physicians' assessment of disease activity
16 was 3.0 (range 0 to 9) for all countries, indicating that disease severity was generally mild (Table 4).
17 The level of disability was low, with mean scores of 0.6 on the HAQ score. However, both physician
18 and patient reported outcomes showed higher levels of disease activity and impact in patients
19 recruited in the UK (Table 4). Across the cohort, 62.2% of patients had at least 1 comorbidity (Table
20 2).
21
22

23 Generally, levels of disease activity were low with a median tender joint count of 2 and swollen joint
24 count of 0. The overall percentage of patients with predominantly enthesitis was 4.8%, with the
25 highest percentages seen in Italy (7.1%) and France (7.0%). The dactylitis scores were similarly low,
26 with most patients in all countries scoring 0. In keeping with a rheumatology clinic population, the
27 majority of patients (91.9%) with a body surface area of psoriasis $< 3\%$. (Table 4).
28
29

30 The physician's assessment of disease activity had the most statistically significant effect on the
31 likelihood of treatment escalation, with an odds ratio of 2.68 for each 1-point increase in score. A
32 high level of correlation was found between variables, including physician's global assessment of
33 disease and the patient reported PsAID-12 score (correlation of 0.64). Using univariate regression,
34 we identified other factors associated with treatment escalation, including patient characteristics,
35 physician characteristics, disease activity and disease impact (Figure 3). Treatment escalation was
36 also more likely in patients who were not already treated with biologic therapies. Only age, tender
37 joint count and comorbidity index were not significantly associated with treatment escalation.
38
39

40 Therefore, a multiple logistic regression model was run with a reduced set of potential factors. When
41 all individually significant factors were included, only five factors were significant in multivariable
42 analysis: physician's assessment, disease duration, non-biological treatment, swollen joint count and
43 EQ-VAS. The inclusion of the PsAID-12 score in this model did not materially affect the results.
44
45

46 Clinicians were asked to rate six possible factors influencing their treatment choice in each case:
47 joint/enthesal activity, skin disease activity, patient-reported outcomes, tolerance of current
48 medication and adherence to current medication. Assessment of joint and enthesal disease activity
49 was perceived to have the highest impact on treatment decisions with markers of systemic
50 inflammation (CRP) being the lowest. In most cases, the clinicians reported that the PsAID score did
51 not significantly influence the decision on treatment escalation beyond these other factors. Where
52 there was an impact on treatment decisions, a review of the PsAID scores was more likely to lead to
53 a decrease in treatment rather than an increase.
54
55

56 The mean CollaboRATE score was 7.96 (maximum possible score 9) indicating a high degree of
57 satisfaction overall, with 52.9% of patients giving the maximum score for satisfaction with their
58 consultation. Generally, PEPPI patient confidence scores were also high with a mean score of 21.4
59 (maximum possible score 25). Similar mean scores for CollaboRATE and PEPPI were seen in those
60

1
2
3 who did and did not have a treatment escalation. However, in patients with low collaborATE scores,
4 treatment escalation only occurred in those with high PsAID scores, whereas in those with high
5 collaborATE scores, even patients with low PsAID scores underwent treatment escalation.
6
7

8 **Discussion:**

9
10 To date, the influence of various patient and clinician factors on treatment decisions for PsA in real-
11 world practice has not been examined. The purpose of the ASSIST study was to investigate the
12 prescribing practice for PsA in routine care and whether the use of the patient reported outcome
13 (PRO), PsA Impact of Disease questionnaire (PsAID-12), impacted treatment decisions in the post-
14 COVID era. The heterogeneity of clinical phenotype and treatment responsiveness in the PsA cohort,
15 alongside the increasing number of effective therapies necessitates collaborative and personalised
16 treatment decision-making.
17

18
19 In this large, multi-centre international analysis, we examine treatment decisions in over 500
20 participants in routine practice, with a particular focus on the role of the PRO PSAID-12.
21 Generalisability was enhanced by including multiple centres across different countries. Nevertheless,
22 all participants were recruited from specialist PsA clinics and disease activity was generally low,
23 which may differ from other rheumatology clinics. It is likely that results may be different in those
24 with more significant skin disease, although this population does seem to reflect most rheumatology
25 clinic populations. [23, 24]
26

27
28 Overall, we found high rates of treatment escalation, one explanation for this is the expansion of
29 treatment options and increasing focus on treat-to-target approaches in recent times. We
30 demonstrate that many aspects of an individual case are considered during treatment decision
31 making. The single factor most associated with treatment change was physician's assessment of
32 disease activity, but swollen joint count, previous medications, disease duration and EQ-VAS were
33 also associated with treatment escalation in multivariable analysis. Clinicians reported that joint
34 counts and assessment of enthesitis were the most common drivers of treatment decisions.
35

36
37 We aimed to examine the influence of PSAID-12 score on decision-making. PSAID has been shown to
38 enable prediction of disease flares in new-onset PsA and prediction of achieving treatment
39 objectives, such as the MDA response [8, 12]. We found that PSAID score correlates with multiple
40 measures of disease severity and there was a significant association between PSAID-12 scores and
41 the odds of treatment escalation. Patients with a higher PSAID-12 score were more likely to have
42 had treatment escalation, however a majority of physicians reported that PSAID-12 had little impact
43 on their clinical decision to escalate treatment.
44

45
46 Most physicians reported that joint counts and assessment of enthesitis were the biggest drivers in
47 treatment decisions. One possible explanation is the inclusion of multiple items in the PsAID
48 questionnaire, only some of which were associated by clinicians with treatment changes (such as the
49 inflamed joint count). Cases where clinicians reported a utility of PSAID-12 scoring in decision-
50 making were related to treatment reduction. With this, PsAID scoring could be used as a tool to
51 increase clinician confidence in treatment de-escalation, it is a quick bedside tool that correlates
52 with multiple measures of disease severity, and
53

54
55 Generally, patients' confidence in their interactions and satisfactions with their consultations was
56 high, reflecting a high satisfaction in the physician effort to understand patient concerns. However,
57 those with higher perceived collaboration were more likely to have treatment escalation in mild
58 cases, perhaps reflecting the identification of otherwise undetected symptoms or concerns.
59
60

1
2
3 Furthermore, it is important to highlight that although most of the researchers in the Assist study did
4 not assign an important role to the PsAID scores in the decision to change treatment, there are
5 already studies that demonstrate the predictive capacity of the PsAID in achieving treatment
6 objectives such as the MDA response.[8] Also, PsAID is able to predict disease flares in recent-onset
7 PsA and as a useful tool in clinical decision making, including treatment decisions.[5]
8
9

10
11 To date, we are not aware of any research about the treatment decisions made in real-world
12 practice in PsA and how patient and clinician factors influence this. Despite an increasing number of
13 effective therapies and regularly updated evidence-based treatment recommendations, the
14 heterogeneity of the disease means that treatment must be personalised. Composite scores (such as
15 the PASDAS) have previously been shown to have an association with treatment change. [8]
16 However such scores were not used in this study to facilitate assessment of individual aspects of the
17 disease and the relationship of these with treatment change. This study has shown that many
18 different aspects of an individual case are considered within a treatment decision in routine practice.
19

20
21 This study reflects real-world practice with over 500 participants in multiple European countries to
22 investigate the factors affecting treatment decisions in daily practice. The participants were
23 recruited using systematic sampling with random starting numbers generated for each site to
24 minimise selection bias. The population thus should accurately reflect a real-world clinic population
25 with low levels of average disease activity and treatment escalation in approximately one-third of
26 patients. However, all participants were recruited in specialist PsA clinics so disease activity and
27 treatment decisions may vary in other rheumatology clinics. Furthermore, the clinics used for this
28 study were face-to-face, which may have affected the type of patients in the study. It is likely that
29 results may be different in those with more significant skin disease, although this population does
30 seem to reflect most rheumatology clinic populations.
31
32

33
34 The enrolment of patients occurred during the years of the COVID-19 pandemic: from July 2021 to
35 March 2022. This potentially had an impact on the patients who were seen in clinic. The pattern of
36 disease seen in clinic could have been different as remote reviews in the pre-covid era were not as
37 common as in the post-covid era, however, the impact of this across the included countries is
38 unclear.
39

40
41 Overall, this study highlights the influence of multiple factors on decision making when reviewing
42 treatments for individuals with PsA. This can help in providing insight into the management of
43 patients with this complex condition.

¹PsAID: 0 to 10, where 0=Best possible score, 10=Worst possible score

²HAQ alternative disability index: 0 to 3, where 0=Best possible score, 3=Worst possible score. Total derived from worst scores in each category

³EQ-5D, VAS for current health: 0 to 100, where 0=Worst possible score, 100=Best possible score

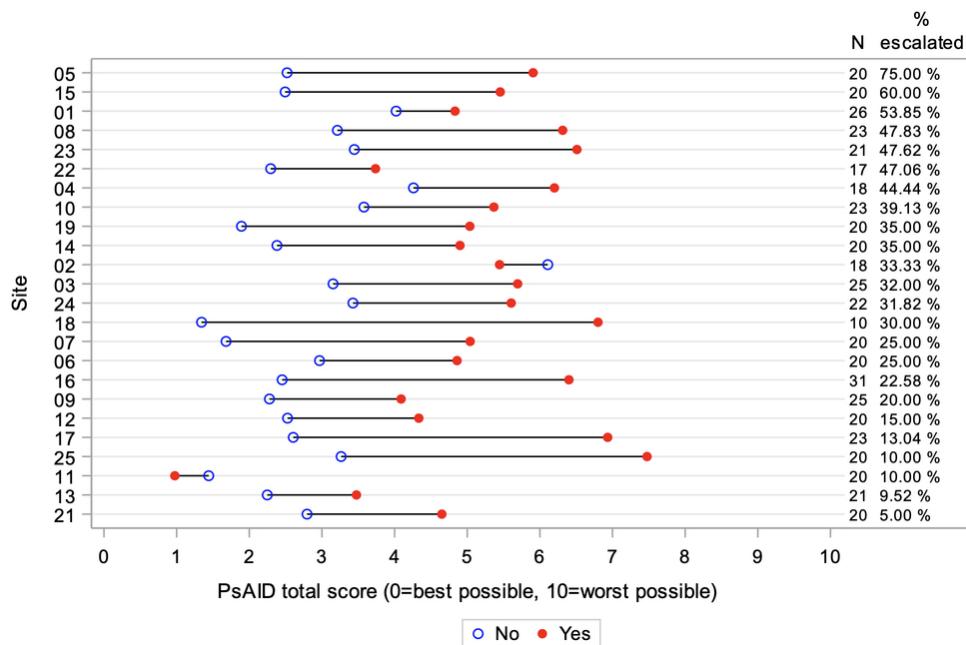

Figure 1. Mean PsAID score by treatment escalation - Graph demonstrating decision of treatment escalation in relation to PsAID score, by treatment site.

Figure 3. Effect of each variable on the odds of treatment escalation - Univariate analysis showing effect of each variable on the odds of treatment escalation.

FCI – functional comorbidity index, AGE – age (years), TJC – tender joint count, DUR – disease duration, DC – Dactylitis Count, SEX – sex, BSA – body surface area psoriasis, LEI – Leeds enthesitis index, HAQ – health assessment questionnaire, SJC – swollen joint count, VAS4 – patient reported skin psoriasis activity, EQV – EQ-5D-5L VAS score, PSA-PsAID, VAS2 – patient reported overall assessment of disease activity, VAS3 – patient reported joint disease severity, VAS1 – patient reported pain score, PHYSASS – physicians assessment of disease activity.

70x49mm (300 x 300 DPI)
